Fig. 1 Climographs (ombrothermic diagrams) for a locality (Rome) of the Mediterranean floristic region, a locality (France) of the Eurosiberian floristic region and a locality (El Cairo) of the Irano-Saharan floristic region. Each climograph displays data for monthly average precipitation and monthly average temperature. The scale of temperature is half of the value of the rainfall scale. Notice that only the Mediterranean locality (Rome) has an intersection of lines (shadowed), i.e. the station has a long dry season in summer.

Biodiversity Primarily Shaped by Geography and Soils

Geographic speciation is predominant in the evolution of plants, which is particularly exacerbated when a territory has numerous geographic features (Fontdevilla, 2014). Indeed, geographic isolation has been particularly effective in the Mediterranean Basin, where numerous islands, peninsulas and high mountains are broadly distributed (Rundel et al., 2016; but see ecological speciation in Fernández-Mazuecos and Vargas, 2010). As a result, a high number of narrow endemics are observed across countries of southern Europe and northern Africa because of strong spatial isolation (Fernández-Mazuecos et al., 2014). Over 10,000 islands (and islets) distributed across the Mediterranean Basin illustrate significant areas for geographic isolation (de Montmollin and Strahm, 2005). The number of capes is even higher (Fig. 2). Abundant opportunities for species isolation have been also provided by high mountains that built up since the Paleogene (Rosenbaum et al., 2002). Species isolation by altitude is also remarkable because mountains about 2000 m above sea level are scattered across southern Europe as a result of plate collision of the three main peninsulas (Iberia, Italian and Balkan) and the European plate in the Tertiary (Hewitt, 2011). Interestingly, these three peninsulas harbored a great deal of plant lineages that became relicts after the glaciations of the Quaternary. In northern Africa, the largest mountain range is the

Fig. 2 Map of the Mediterranean floristic region (shadowing). This map is based on Ecoregions 2017 © *Resolve* (<https://ecoregions2017.appspot.com/>) with some modification from Vargas and Kadereit (2001).

Atlas, which is the result of orogenic movements finally uplifted in the Miocene (Babault et al., 2008). The east–west orientation of most of these mountain ranges hindered north–south migrations during glaciations in most of the territory except for central Italy and Greece. Additionally, the east–west orientation of the Mediterranean Sea has also been a significant geographical barrier for plant dispersal between North Africa and Europe, with exceptions of land proximity on the straits of Gibraltar and Tunisia–Sicily (Rodríguez-Sánchez et al., 2008; Rodríguez-Sánchez and Arroyo, 2011).

As a result of the Mediterranean geographic setting, most narrow endemics are found either on islands or medium-high mountains (Lavergne et al., 2004; Fernández-Mazuecos et al., 2014; Jiménez-Mejías et al., 2015). Indeed, migration barriers have been responsible for patterns of isolation, including recent-most differentiation of subspecies inferred by phylogeographic analyses (Vargas, 2003). Species (phylogenetic) differentiation is associated with geographic isolation over longer periods of time (Vargas et al., 2018). Therefore, taxonomic ranks (genera, species, subspecies) appear to be a reliable proxy to generate evolutionary hypotheses.

Speciation of Mediterranean plants is also clearly linked to soil types, which determine geographic occurrence of plants (Thompson, 2005). Botanists consider two basic soil types related to plant distribution. On the one hand, Cenozoic deposits of calcareous sediments resulted in extensive plains and coastal mountains. On the other hand, inland mountains are primarily made of acid soils derived from granites, shales and sandstones. Indeed, the majority of species are well adapted mainly to limestone (calcareous) or acidic soils (granites, shales, sandstones), while a lower number of species are competitive on both substrates (soil tolerant plants). Therefore, the two main soil types (calcareous vs. siliceous) are good predictors of plant distribution. Plants are also adapted to saline soils (halophilous species) extensively found along the 46,000 km of Mediterranean coast, which offers an interesting linear system to test evolutionary and phylogeographic hypotheses (Kadereit et al., 2005). Adaptation to gypsum soils is particularly interesting in the Mediterranean region given that many edaphoendemics are found narrow in areas of northern Africa, the Iberian Peninsula and Anatolia (Escudero et al., 2015). Soil requirements are exacerbated in Mediterranean (vs. Eurosiberian) conditions because nutrient uptake is limited by lack of water, which primarily occurs in the 2–4 months of summer (Lamont, 1982). The same is true for serpentine soils (Oyornate, 2008), although speciation is low because they are scarce in the Mediterranean Basin. Given that plant isolation is related to both edaphic adaptation and geographic confinement, the question remains as to whether geography or soils have been the most significant drivers of speciation (Molina-Venegas et al., 2013).

Pollination is one of the most developed disciplines in the search for ecological factors promoting diversity of Mediterranean flowering plants because insect diversity parallels that of flowering plants. Although the Mediterranean Basin mostly lacks vertebrate pollinators, unlike in other Mediterranean floristic regions (primarily South Africa), abundance and diversity of insect pollinators entail intense evolutionary pressures as revealed by a considerable range of flower forms and differential phenologies (Herrera, 1992). Flowers with a high level of generalization are common in Mediterranean areas (Gómez et al., 2007) coexisting with

Fig. 3 Snapdragons (*Antirrhinum*) show the most occluded corolla of angiosperms, and bees are the main pollinators of the 24 snapdragon species. Photo of *A. graniticum* pollinated by *Xylocopa violacea* in Colmenar Viejo (Spain).

some of the most specialized flowers of angiosperms such as *Ophrys* and *Antirrhinum* (Vargas et al., 2017) (Fig. 3). Numerous reproductive systems and flower morphologies suggest that pollination shifts are responsible for a significant part of plant diversity in the Mediterranean Basin.

Mediterranean Floristic Richness

The Mediterranean Basin harbors a rich flora of over 24,000 species (Greuter, 1991) in a large territory that accounts for 75% (2,300,000 km²) of global Mediterranean-type floristic regions (Rundel et al., 2016). Using floristic of data, we estimated a total of around 2000 genera and 200 families for the native species of the Mediterranean floristic region (Euro+Med, 2006; Greuter et al., 1986–1989; Tutin et al., 1964–1980). At the genus level, species diversity is also deeply uneven with a great deal of monospecific genera co-occurring with hyperdiverse genera. For example, botanists recognize 27 monospecific angiosperm genera of a total of around c. 1132 genera (c. 5537 species) for the Iberian Peninsula (Aedo et al., 2017). In contrast, some other genera are hyperdiverse in the Mediterranean Basin: *Astragalus* (429 spp.), *Centaurea* (533 spp.) (Fig. 4), *Hieracium* (547 spp.), *Satureja* (124 spp.), among others (data from Greuter et al., 1986–1989; Greuter and Raab-Straube, 2008).

Fig. 4 The genus *Centaurea* with over 500 species is one of the most diverse in the Mediterranean Basin. Photo of *C. ornata*, Madrid, Spain.

About 700 woody species are distributed across the Mediterranean Basin (Fady and Conord, 2010). The Fabaceae, Lamiaceae, and Cistaceae provide the highest number of shrub species, while trees are mostly found in the Fagaceae, Pinaceae, Rhamnaceae, Rosaceae and Salicaceae. The diversity of tree species is, however, low (c. 220 species) in comparison with other biomes at similar latitudes (Médail et al., 2019). Numerous annual herbs (up to 50% in some local floras) are found in the Asteraceae, Brassicaceae, Caryophyllaceae, Lamiaceae and Poaceae (Fiz et al., 2002). The high number of endemic species (6318 spp.) indicates successful isolation of populations relatively long-term (Greuter, 1991). A low number of species (2.5%) are introduced, which indicates that the Mediterranean flora is really competitive against aliens.

Proportional levels of vascular plant diversity have been recorded in countries of the eastern (Greece, 5000 spp.), middle (Italy, 5600 spp.) and western (continental Spain, 5050 spp.; Morocco 3675 spp.) Mediterranean Basin (Davis et al., 1994). A detailed analysis shows similar levels of species–area relationship between Spain and Greece, which have medium levels in comparison to the other four Mediterranean floristic regions (Cowling et al., 2015). The Mediterranean region shows richer levels of species diversity than nearby floristic regions. However, the highest diversity is found when the Eurosiberian and the Mediterranean regions meet on the northernmost limit (Fig. 2). This boundary is easier to be established when mountain ranges shape more extreme climatic conditions that fit into Eurosiberian (cold winter, rain all year round) and Mediterranean (rainy winter, dry summer) conditions. However, botanists do not always agree about the boundary at lowland areas.

Two floristic topics still under investigation are: (i) delimitation of the Mediterranean region boundaries, and (ii) addition of peripheral territories to the Mediterranean floristic region. On the one hand, boundaries of the Mediterranean region with the Euro-siberian region on the north (Europe) and the Saharan region on the south (Africa) have been fluctuating over the last millions of years as a result of climate change (Fig. 2 for estimated limits). On the other hand, the floras of Macaronesian islands challenge the classification of floristic regions of Europe and Africa (Takhtajan, 1986). While Azores has a strong European (Atlantic) floristic connection, the Canary Islands close affinities with the Mediterranean floristic region and the Cape Verde islands with the Sahara. Recognition of Macaronesia as a group of archipelagos conforming its own floristic region, rather than each archipelago included in continental floristic regions, is still under debate (Takhtajan, 1986; Finnie et al., 2007; Rivas-Martínez, 2009).

Plant relationships between floras as well as key species help delimit floristic regions. In particular, presence of the Mediterranean olive tree (*Olea europaea* L. subsp. *europaea*) is considered by paleobotanists as the best indicator of mediterraneity in natural areas of the Mediterranean Basin (Carrión et al., 2010). The natural range of this olive is indeed used to define the extent of the mediterranean climate (Besnard et al., 2013; Carrión et al., 2010). Interestingly, *Olea europaea* is also distributed in Madeira (subsp. *cerasifomis*) and the Canary Islands (subsp. *guanchica*), which indicates relatively old climatic connection between Mediterranean and Macaronesian lowland areas. Additional signal of mediterraneity is given by the fact that countries of the other four Mediterranean floristic regions of the world easily cultivate the olive tree and other Mediterranean crops. One more example is given by the holm oak (*Quercus ilex*) and relatives (*Q. rotundifolia*, *Q. calliprinus*, *Q. coccifera*) (Fig. 5), which are dominant trees in lowland areas and suggest historical mediterranean conditions (Ochando et al., 2019). All these trees have played a central role in both diet and vegetation of human cultures over millennia.

Fig. 5 The genus *Quercus* has numerous species dominant in Mediterranean vegetation types. Photo of *Q. coccifera*, Madrid, Spain.

Biogeography at the Cross-roads of Three Continents

Historical biogeography reveals that the flora of the Mediterranean region is a melting pot of plant lineages from Europe, Africa and Asia that survived and differentiated primarily as a result of geography and recent climatic events. The four last glaciations that took place in the Pleistocene not only drove numerous lineages of plants to extinction but also vegetation communities. As a result, the Mediterranean Basin harbors numerous floristic lineages of Pliocene and Quaternary origin coupled with a few ancient lineages from pre-mediterranean epochs (Vargas et al., 2018). Four waves of extinction during the Cenozoic and Quaternary took a toll on many lineages: tropical elements by emergence of strong seasonality in the middle Miocene (16–14 Ma); tropical and subtropical elements by aridification during the Messinian Salinity Crisis (6–5 Ma); and mesic elements by cool temperatures and drying during Quaternary glaciations (<2.5 Ma) (Postigo-Mijarra et al., 2009; Barrón et al., 2010). Thus, descendent lineages of the Cenozoic paleoflora that once occupied wide areas of warm temperate rainforests and swamp forests of the Northern Hemisphere compose only a small part of the modern flora (Rundel et al., 2016). Intensification of seasonality and the onset of a full Mediterranean-type climate in the Pliocene and Pleistocene were associated with the disappearance of many paleotropical and mesic temperate forest taxa and gave way to the Mediterranean-type vegetation that exists today. Indeed, there is paleobotanical and phylogenetic evidence for early mediterranean conditions in some areas of southern Europe during the Miocene (Vargas et al., 2018), followed by the establishment of a mediterranean climate across the Mediterranean basin in the last 2.8 million years (Suc, 1984). This, together with extinctions during Quaternary glaciations, gave plants new environment opportunities to differentiate. The lack of angiosperm families endemic to the Mediterranean Basin, with the exception of the monotypic carnivorous *Droserophyllaceae*, supports the explanation of failure of long-term isolation and relatively recent immigration of many lineages. Nevertheless, several paleotropical lineages—for example, *Myrtus* (Myrtaceae) (Fig. 6), *Phillyrea* (Rhamnaceae), and *Pistacia* (Anacardiaceae)—overcame the environmental and climatic challenges of the late Cenozoic and remained as widespread components of the modern flora in the region (Barrón et al., 2010).

Plant connection between the northern (Europe) and southern (Africa) sides of the Mediterranean region has been challenged by dispersal biogeography. Current studies of biogeography test two competing hypotheses when analyzing plant disjunctions: vicariance as a result of the opening of the Strait of Gibraltar and subsequent refilling of the Mediterranean Basin (Zanclean flood) and long distance dispersal (Sanmartín, 2014). Phylogenetic and phylogeographic studies indicate that the Mediterranean Sea has been a permeable barrier for many plants (Rodríguez-Sánchez et al., 2008) irrespective of diaspore dispersal syndromes (Guzmán and Vargas, 2009).

Historical biogeography helps understand the geographic distribution of plants in an evolutionary framework, in which ecological requirements are also analyzed (Sanmartín, 2014). The woody flora of the Mediterranean region shows that not only adaptation but also phylogenetic constraints and lineage age are of substantial importance for explaining covariation among life-history traits and associated ‘character syndromes’ in plant communities (Herrera, 1992). Ecological results reveal that many key traits considered as plant response to mediterranean climates are found in leaves (Paula and Pausas, 2006; Guzmán et al., 2009). Indeed, one of the distinctive features of Mediterranean-type plants of the world is sclerophylly: thick, tough leaves with thick cuticles and small, thick-walled cells (Paula and Pausas, 2006). Although phylogenetic evidence of rapid speciation associated with the non-sclerophyllous plants (herbs) was found, a syndrome-driven local diversification has also been described for shrublands under mediterranean conditions (Verdú and Pausas, 2013). Rapid diversification has been referred to as plant radiation, which should be reflected in a greater morphological and/or physiological divergence among species in brief periods of rapid diversification from a single

Fig. 6 Despite the family Myrtaceae has a single species in the Mediterranean floristic region, time-calibrated phylogenies reveal that the myrtle (*Myrtus communis*) forms a paleotropical lineage. Photo taken in Chipre (by M. Luceño).

Fig. 7 Representatives of the adaptive radiation of rockroses (*Cistus* spp.): (A) *C. clusii* (Spain); (B) *C. ladanifer* (Spain); (C) *C. laurifolius* (Spain); (D) *C. monspeliensis* (Spain); (E) *C. creticus* (Morocco); (F) *C. crispus* (Morocco).

ancestor. Some of the best examples have been found in herbaceous plant groups well represented in the Mediterranean Basin (*Astragalus*, *Centaurea*, *Dianthus*, *Silene*, *Ophrys*), rivaling or exceeding the fastest known global plant radiations (Valente et al., 2010; Breitenkopf et al., 2015). Geographic speciation is closely associated with plant ‘radiation’ in the Mediterranean, while ecological factors are considered responsible for species ‘adaptation’, i.e. both together meet the conditions for ‘adaptive radiation’ (Schluter, 2000). The first example of adaptive radiation of Mediterranean plants was described in *Cistus* (Guzmán et al., 2009) (Fig. 7), one of the most characteristic bushes in vegetation dynamics after Mediterranean woodland deforestation.

Vegetation Dynamics

The vegetation of the Mediterranean floristic region is dominated by evergreen trees and shrubs adapted to survive long hot summers without rainfall. Rich floristic regions have historically challenged a practical classification of plant communities (Dallman, 1998). Indeed, plant richness across the Mediterranean Basin region not only outnumbers that of the other mediterranean floristic regions of the world given that it covers a territory that is 75% of all Mediterranean-climate countries, but also entails a greater number of habitats (c. 150) (Sundseth, 2009). Similarly to plant evolution, the three main drivers of plant community

assemblages are geography, topography and soil types. Indeed, vegetation across the Mediterranean Basin is clearly determined by base- or acid-rich soils that filter species distributions (Oyonarte et al., 2008).

Early phytogeographers of the 18th century such as Linnaeus and Soulavié described the distribution of European plants into altitudinal patterns of vegetation (vegetation belts) (Egerton, 2018). Subsequent description of plant distributions and altitudinal zonation was applied to any mountainous territory of the world (Humboldt, 1807). In particular, there is agreement in recognizing five vegetation belts in the Mediterranean region: (1) coastal scrub (maquis/garrigue/phrygana) and conifer-oak woodlands on inland hills (thermo-Mediterranean vegetation belt); (2) sclerophyll woodland on plains and piedmont (meso-Mediterranean); (3) oak and pine woodlands up to the altitudinal timberline (supra-Mediterranean); (4) high-altitude bush communities (oro-Mediterranean); and (5) alpine communities of herbs (cryoro-Mediterranean).

Thermo-Mediterranean vegetation belt—Coastal scrub called *maquis* (dense shrubs) and *garrigue* (scattered shrublets) in western countries (Fig. 8) and *phrygana* in Greece (Fig. 9) is dominant, although the climax is believed to be reached when woodlands of the olive tree (*Olea europaea*), the carob tree (*Ceratonia siliqua*) and pine trees (*P. halepensis*, *P. pinea*) find optimal conditions. Communities at this altitude are analogous to those of the basal belt of the Eurosiberian region. Most representative plants are classified mainly in eight angiosperm families of bushes that are distributed in patchy patterns after tree deforestation: Anacardiaceae (*Pistacia* spp.); Cistaceae (species of *Cistus*, *Halimium*, *Helianthemum* and *Fumana*); Euphorbiaceae (*Euphorbia acanthothamnus*, *Euphorbia dendroides*); Fabaceae (species of *Genista*, *Ulex*, *Stauracanthus*, *Calicotome*); Lamiaceae (*Rosmarinus officinalis*, *Thymus* spp., *Salvia* spp.); Myrtaceae (*Myrtus communis*); Palmaceae (*Chamaerops humilis*); Rhamanceae (*Rhamnus* spp.); and Rosaceae (*Sarcopoterium spinosum*). Despite human deforestation, some woodland areas of conifers (*Pinus pinea*, *Pinus halepensis*, *Juniperus phoenicea*, *Juniperus oxycedrus*) are still preserved and even favored because human activities for timber. Many herbaceous species in the Asteraceae (e.g. *Asteriscus maritimus*, *Pallenis spinosa*, *Carlina corymbosa*, *Centaurea alba*), Poaceae (e.g. *Brachypodium pinnatum*, *Hyparrhenia hirta*, *Lamarckia aurea*, *Aira caryophyllea*, *Vulpia bromoides*) and Euphorbiaceae (*Euphorbia characias*) are widespread. The oleander (*Nerium oleander*) and tamarisks (*Tamarix* spp.) occur when ravines cross the coastal scrub of the phrygana (east) and maquis (west).

Meso-Mediterranean vegetation belt—The altitude zone between 300 and 800 m.a.s.l. is dominated by evergreen trees and shrubs. They form sclerophyll woodlands on mountain foothills analogous to the lower montane belt of the Eurosiberian region. These woodlands are less patchy than coastal groves because of dominance of particular trees such as the helm oak (*Quercus ilex*/*Q. calliprinos*) in drier areas (Fig. 10), while other *Quercus* species are predominant in western oceanic areas (*Q. suber*) (Fig. 11) and gypsum soils (*Q. coccifera*) (Fig. 5). They group together with some other small trees such as the Judas tree (*Cercis siliquastrum*), the Christ's thorn (*Paliurus spina-christi*) (Fig. 12), the smoke tree (*Cotinus coggygria*) (Fig. 13) in eastern Mediterranean areas. Ecological succession at this vegetation belt includes numerous species of heathers (*Erica* spp.) and rockroses (*Cistus* spp.) on acidic soils, while legume scrub (*Ulex minor*, *Genista scorpius*, *Spartium junceum*), a rockrose (*Cistus albidus*) and a blue-flowered shrublet (*Aphyllanthus monspeliensis*) find optimal conditions on basic soils. The plane tree (*Platanus orientalis*) in the east, poplars (*Populus* spp.) in the west and the elm tree (*Ulmus minor*) across the Mediterranean Basin are dominant trees when streams cross this vegetation belt.

Supra-Mediterranean vegetation belt—Few tree species dominate in high mountains between 800 and 1700 m.a.s.l., which form extensive woodlands analogous to the upper montane belt of the Eurosiberian region. Almost monospecific forests of pine trees (*Pinus sylvestris*, *P. nigra*, *P. uncinata*, *P. heldreichii*) accompanied by some other conifers (*Cedrus atlantica*, *C. libanii*, *Abies pinsapo*, *A. nebrodensis*, *A. cephalonica*, *Cupressus sempervirens*) are observed at high altitudes of Mediterranean mountains, which reach

Fig. 8 Coastal vegetation in the thermo-Mediterranean vegetation belt of the western Mediterranean (Almería, Spain).

Fig. 9 Herbivorism, together with fire and human activities, has shaped the landscape of the phrygana and other vegetation types since time immemorial. Photo taken in Crete (eastern Mediterranean Basin).

Fig. 10 The meso-Mediterranean vegetation belt is well recognised by the presence of the helm oak tree (*Quercus ilex*). Photo taken in Sierra de Guadarrama, Spain.

timberline around 1700 m.a.s.l (Fig. 14). There is a mixed temperate forests of conifers, oaks (*Quercus pyrenaica*, *Q. pubescens*, *Q. macrolepis*), strawberry trees (*Arbutus unedo*, *A. andrachne*) and a prickly juniper (*Juniperus oxycedrus*). When degradation occurs, the ecological succession shows numerous legume bushes (*Genista* spp., *Cytisus* spp.), rockroses (*Cistus laurifolius*) (Fig. 7C), the common box (*Buxus sempervirens*) and heathers (*Erica* spp.), followed by numerous herbaceous species after further degradation (Fig. 15). The herbaceous layer is often dominated by a cosmopolitan fern (*Pteridium aquilinum*), numerous sedges (*Carex* spp.) and grasses (Poaceae). Although ravines and valleys harbor also tree species of lower altitudes, some trees (*Alnus glutinosa* on acidic soils; *Aesculus hippocastanum* in the east) and several species of willows (*Salix* spp.) form dense riparian vegetation.

Fig. 11 The cork tree (*Quercus suber*) is distributed in mesic areas exclusively of the western Mediterranean region.

Fig. 12 Some endemic species, such as the Christ's thorn (*Paliurus spina-christi*), are distributed in the eastern Mediterranean Basin in the meso-Mediterranean vegetation belt. Photo taken in Mount Parnassus (Greece).

Oro-Mediterranean vegetation belt—Tall trees cannot cope with climatic conditions at altitudes between 1700 and 2100 m.a.s.l. Therefore, groups of bushes and dwarf trees are the biggest plants. Monospecific dense scrub is common in all Mediterranean mountains, which delimits a vegetation belt analogous to the subalpine belt of the Eurosiberian region. Legume bushes (*Genista cinerea*, *Cytisus* spp., *Echinopartum* spp.) are common in the west, while spiny *Astragalus* species and the barberry (*Berberis* spp.) form the scrub in the east (Fig. 16). Degradation of bushes leads to pastures, which is often the result of natural fires (storm lightning) that brought about herbaceous species adapted to burnt soils. Mediterranean grasslands of the oro-Mediterranean belt are dominated by species of fescues (*Festuca*) in dry soils and matgrass (*Nardus stricta*) in humid habitats.

Cryoro-Mediterranean vegetation belt—High-mountain plants at altitudes over 2100 m form part of communities analogous to those of the alpine belt of the Eurosiberian region. Dominant prairies on the top of the mountains have perennial species of herbs (Fig. 17), of which many are shared with Eurosiberian mountains because some ecological characteristics in common. However, herbs of Mediterranean mountains suffer from environmental uncertainty given that scarce snow does not help protect plant tissues from deep temperature variation including frost. A high number of endemics of a few genera are found in this vegetation belt together with numerous species shared in many Mediterranean and Eurosiberian mountains (*Agrostis*, *Alchemilla*, *Androsace*, *Carex*, *Hieracium*, *Linaria*, *Minuartia*, *Saxifraga*, *Silene*, *Viola*).

Fig. 13 Not all species that form characteristic vegetation types are endemic to the Mediterranean Basin. For instance, the smoke tree (*Cotinus coggygria*) is distributed from the eastern Mediterranean to the Himalayas. Photo taken in Mount Olympus (Greece).

Fig. 14 Some conifers such as the Heldreich's pine (*Pinus heldreichii*) reach timberline in Mount Olympus (Greece).

Conservation

When woodlands are dramatically altered by fire or human activities, the ecological succession at low and medium altitudes takes place from pastures, followed by shrubs and then woodlands after about a century of natural restoration. Monospecific woodlands or mixed forests appear to be the climax in the three lower vegetation belts of the Mediterranean floristic region. Trees cannot survive at high elevations, which results in a shorter ecological succession from grassland to bush communities (oro-Mediterranean) or even

Fig. 15 Predictable ecological succession occurs after degradation of oak woodlands (*Quercus pyrenaica*) of the Iberian Peninsula, and then legume bushes (*Genista florida*) and rockroses (*Cistus laurifolius*) take over. Photo taken in Miraflores (Spain).

Fig. 16 The oro-mediterranean vegetation belt of Sierra de Gredos (central Iberia) shows large areas of legume scrub (*Cytisus oromediterraneus*).

shorter from a type of alpine prairie to another (cryoro-Mediterranean). At lower elevations, the floras and vegetation types observed today have been dramatically shaped by long human activity, more than in any other Mediterranean floristic region of the world because of more than 10,000 years of domestication, plant cultivation, livestock spread and fire. Natural fires have been a significant agent of driving plant evolution since the Miocene, although current landscapes shaped by fire in the Mediterranean has been recently favored by human activities (Rundel et al., 2018). Conservation of pristine Mediterranean woodlands is one of the priorities by the European Commission (Natura, 2000).

Fig. 17 Neither trees nor bushes are found in the cryoro-Mediterranean vegetation belt (*Sierra de Guadarrama*, central Iberia), where short herbs and cushion-like plants can cope with extreme climatic conditions, including environmental uncertainty brought about by short-lasting snow cover.

Despite human pressure during millennia, conservation of numerous species and areas is still feasible and should be urgently prioritized (Nature and Biodiversity, 2019). On the one hand, it has been estimated a relatively low number of extinctions (32 species in the Mediterranean Basin), although most countries report about a fourth of floras threatened as applying IUCN criteria (Greuter, 1994). Some of the Critically-Endangered species of the Mediterranean belong to monospecific genera such as the five Iberian genera (*Avellara*, *Castrilanthemum*, *Gadoria*, *Gyrocarum*, *Naufraga*), which have been considered as ‘endangered living fossils’ that need the most urgent conservation measures (Vargas, 2010; Vargas et al., 2019). On the other hand, eight large hotspots have been found across the Mediterranean Basin: Moroccan Atlas, Baetic-Rifaen complex, Tyrrhenian islands, Greece, Crete, Anatolia and Cyprus, Syria-Lebanon-Israel and Mediterranean Cyrenaic (Médail and Quézel, 1997). Most of the 52 putative refugia within the Mediterranean region obtained from the analysis of the phylogeographical patterns of 82 plant species are included in these eight large hotspots (Médail and Diadema, 2009). Floristic and genetic data provide suitable tools to propose conservation of particular areas as a priority given that human pressure still increases every year.

Abstract

Grasslands are spontaneously occurring herbaceous vegetation types that are mostly dominated by grasses or other graminoids and have usually > 10% herb-layer cover, while woody species are absent or have a significantly lower abundance than the herbs. In the Palaearctic biogeographic realm, natural and secondary grasslands (76% and 24% of all grasslands, respectively) cover about 10.0 million km², i.e., 18% of its territory, which constitute 41% of global grasslands—more than any other biogeographic realm. In “The encyclopedia of the world’s biomes,” the Palaearctic grasslands are placed in the section “Grasslands and shrublands,” where we defined 10 regions, which are treated in individual chapters: Western Europe, Northern Europe and Baltic States, Eastern Europe, Mediterranean Region, Middle East and Caucasus, Russia, Kazakhstan and Middle Asia, Mongolia, China, and Japan. These regions cover the huge majority of the realm and about 98% of its grasslands. Each chapter describes the extent, physiogeography, origin, biodiversity and typology of the grasslands in the region, the threats for grassland diversity and extent, as well as grassland management and conservation. Grasslands are important habitats for many groups of taxa. Dry calcareous grasslands and steppes constitute habitat of most of Europe’s butterfly and *Orthoptera* species, and they host significant number of European endemic plants. In small spatial scales (i.e., below 100 m²) Palaearctic grasslands, especially meso-xeric ones, can hold even higher species diversity of plants than tropical rainforests. However, Palaearctic grasslands are also among the most intensively and negatively human-impacted habitats. Changes in grassland management, like overgrazing or other types of intensification as well as abandonment were assessed as the most important recent and future threats. Other important reasons of decline in grassland diversity are habitat loss and altered site conditions. The negative impact of climate change and invasive species is predicted to be stronger in the future. In the last years, various conservation efforts to monitor, maintain and promote grassland extent and diversity were made. However, to counteract the negative trends, these efforts urgently need to be intensified and their efficiency needs to be improved.

Introduction

The Palaearctic biogeographic realm is the largest terrestrial realm on Earth (Olson et al., 2001; see Fig. 1), and grasslands cover a substantial fraction of its territory. The grasslands of the Palaearctic are of diverse type and origin, i.e., natural, semi-natural or anthropogenic. They are a major basis for human food supply and at the same time host a high biodiversity. In this article, we provide an overview on the major grassland types of the realm, including information on origin, spatial extent, and biodiversity.

Fig. 1 Delimitation of the Palearctic biogeographic realm according to [Olson et al. \(2001\)](#) combined with the biome classification of [Bruehlheide et al. \(2019\)](#), largely based on [Schultz \(2005\)](#) (map kindly provided by C. Marcenò). Note that according to other concepts, the “Subtropics with year-round rain” do not reach as far north and, for example, most of Japan would belong to the Temperate midlatitudes.

In addition, we outline the causes of regional differences among these factors including the major drivers of biodiversity loss. We largely summarize the knowledge assessed for ten specific chapters on grasslands in different regions of the Palearctic and some previous syntheses (e.g., [Dengler et al., 2014](#); [Wesche et al., 2016](#); [Török and Dengler, 2018](#)). Both the individual chapters and the synthesis have been organized by the Eurasian Dry Grassland Group (EDGG), an international organization dealing with ecology and conservation of all types of natural and semi-natural grasslands of the Palearctic (**Box 1**).

In “The encyclopedia of the world’s biomes,” the Palearctic grasslands are placed in the section “Grasslands and Shrublands.” We defined ten regions, which are treated in individual chapters (Western Europe: [Boch et al., 2020](#); Northern Europe and Baltic States: [Dengler et al., 2020b](#); Eastern Europe: [Török et al., 2020](#); Mediterranean Region: [Guarino et al., 2020](#); Middle East and Caucasus: [Ambarlı et al., 2020](#); Russia: [Tishkov et al., 2020](#); Kazakhstan and Middle Asia: [Wagner et al., 2020](#); Mongolia: [Pfeiffer et al., 2020](#); China: [Li et al., 2020](#); Japan: [Ushimaru et al., 2020](#)). The regions cover the huge majority of the Palearctic biogeographic realm and about 98% of its extant grasslands (**Fig. 2** and **Table 1**). For practical reasons, we delimited the chapters mostly based on political borders, i.e., by combining countries with similar physical geography and/or land-use history. Only the chapter of the Mediterranean Region ([Guarino et al., 2020](#)) and partly the one of Western Europe ([Boch et al., 2020](#)) apply a more biogeographic delimitation by including some countries only partly (**Fig. 2**).

The focus of the grassland chapters are natural and semi-natural grasslands and largely exclude arctic-alpine grasslands. However, to provide a comprehensive overview and for consistency reasons, in this synthesis we also cover intensified as well as arctic-alpine grasslands.

Box 1 The Eurasian Dry Grassland Group (EDGG).

The Eurasian Dry Grassland Group (EDGG; <http://www.edgg.org>), an official working group of the International Association for Vegetation Science (IAVS), was founded in 2008. It has 1314 members, both scientists and conservation practitioners, from 64 countries over the whole Palaearctic (September 2019). With a membership free of any charge, the EDGG coordinates international research on the biodiversity, ecology and conservation of all natural- and semi-natural grasslands of the Palaearctic and initiates respective policy actions. The EDGG is governed by an Executive Committee currently with eight chairs, elected by the membership for 2-years terms. The EDGG facilitates the communication between members by using its mailing list and its open-access electronic journal *Palaearctic Grasslands* with editorial peer review that currently appears in five issues annually. The EDGG organizes yearly conferences (Eurasian Grassland Conferences, EGCs) and Field Workshops (Research Expeditions) for its members. The EDGG is strongly involved in facilitation the establishment of national grassland databases and started the realm-wide database GrassPlot (<https://bit.ly/2HvVkgu>) with the aim of joining standardized multi-scale datasets collected during the Field Workshops with comparable datasets from other projects to support grassland research and macroecological studies in grassland biodiversity. The EDGG is very active in organizing and publishing thematic issues and special features in and with internationally recognized journals and publishers.

Delimitation and Physical Geography of the Region

According to the biogeographic classification by Olson et al. (2001), the Palaearctic biogeographic realm comprises > 52 million km² on three continents, Europe, Asia, and Africa (Fig. 1 and Table 1). It extends over > 20,000 km from west to east (30°W on the Azores to 170°W in the Russian Far East) and over 7000 km from north to south (81°N on Franz-Josef Land in the Arctic Ocean to 17°N on the Arab Peninsula). Thus, the highest (Mt. Everest, 8846 m a.s.l.) and the lowest point (shores of the Dead Sea; 431 m b.s.l.) of the terrestrial surface of the Earth are covered.

The Palaearctic biogeographic realm comprises all terrestrial biomes (Bruehlheide et al., 2019) except the “Tropics with year-round rain” (Fig. 1). While the “Subtropics with year-round rain” only occur in East Asia and the “Tropics with summer rain” can only be found in the Southern part of the Arab Peninsula, the other seven biomes are widely distributed: the “Boreal zone,” the “Temperate midlatitudes,” the “Dry midlatitudes” and the “Dry tropics and subtropics” are the most extensive, the “Polar and subpolar zone,” the “Alpine biome” and the “Subtropics with winter rain” (also known as “Mediterranean biome”) cover a smaller area. The climate in the Palaearctic biogeographic realm is very diverse. According to the Köppen–Geiger climate classification system the continental climates (group D) prevail in the realm, mostly warm-summer humid continental climate (Dfb) and subarctic climate (Dfc), that are present from Central Europe to the Bering Sea (respectively in the western and in the eastern most parts of the realm). In Western Europe and within several areas of south-eastern borders of the Palaearctic realm, and in South Japan also temperate climates occur (group C). Dry climates (group B) dominate major parts of Central Asia, Mongolia, north-western China, the Middle East, the Arab Peninsula and North Africa (Kottek et al., 2006). The Eastern part of the realm is influenced by the monsoon circulation resulting in large seasonal precipitation variability. In the northernmost regions and in mountain ranges of the realm also polar and alpine climates occur (group E). Mean annual temperature ranges from −29.3 °C to +31.0 °C, and mean annual precipitation from close to 0–3722 mm (Hijmans et al., 2005). Given the huge latitudinal and elevational gradients, it is not surprising that bedrocks and soils are highly variable.

Origin and Extent of the Grasslands

Definition and Types of Grasslands

There are many different definitions of grasslands from ecological, physiognomic, agronomic or remote-sensing points-of-view (Gibson et al., 2009; Dixon et al., 2014; Wesche et al., 2016; Török and Dengler, 2018), which in turn have considerable impact on measuring the spatial extent of grasslands. Here, we follow a slightly modified version of the definition of Török and Dengler (2018), based on earlier suggestions by Janišová et al. (2011) and Dengler et al. (2014):

Fig. 2 Subdivision of the Palearctic biogeographic realm into regions corresponding to chapters in this “Encyclopedia” and/or used in tables and figures of this chapter. The 10 colored regions correspond to one of the EDGG-edited grassland chapters in the “Encyclopedia,” while the *white* and *gray* regions are not treated in a specific chapter (map prepared by I. Dembicz).

Grasslands are spontaneously occurring herbaceous vegetation types that are mostly dominated by grasses (*Poaceae*) or other graminoids (*Cyperaceae*, *Juncaceae*) and have a relatively high herb-layer cover (usually > 10%), while woody species (dwarf shrubs, shrubs and trees), if present at all, have a significantly lower cover than the herbs.

With “spontaneously occurring,” we exclude artificial grasslands that are reseeded every year, such as cereal fields (which otherwise would meet the definition). Deviating from Török and Dengler (2018), we lowered the minimum vegetation cover in the definition from 25% to 10% to match the definition used by FAO (2019). This means that now also desert steppes are fully covered.

Based on their origin, there are two main and five subordinate categories of grasslands (Dengler et al., 2014; Török and Dengler, 2018; see Fig. 3):

- (1) *Natural grasslands* (occurring in places where the natural vegetation would also be a grassland, though the current grasslands are potentially modified through human land use)
 - (1a) *Steppes* (climatogenic grasslands in climates that are too dry to sustain forests and are affected by frost) (Fig. 3A).
 - (1b) *Arctic-alpine grasslands* (climatogenic grasslands in climates that are too cold to sustain forests) (Fig. 3B).
 - (1c) *Azonal and extrazonal grasslands* (pedogenic or topogenic grasslands that occur under special soil or topographic conditions that, at small spatial scales, allow grassland to exist in climates that otherwise would support forests, shrublands or deserts; azonal grassland types are those that nowhere form the zonal vegetation, but occur in similar form across two or more biomes, whereas extrazonal grasslands in one biome are similar to zonal grasslands, i.e., steppes or arctic-alpine grasslands, in another biome). Examples of azonal grasslands are salt marshes and coastal dunes (Fig. 3C), while a typical example of extrazonal grasslands are the steppic grasslands that occur on steep south-facing slopes in the forest climate of central Europe (Fig. 3D).

The delimitation of the 13 regions is shown in Fig. 2. Ten of the regions are covered in regional chapters, except the three regions set in italics. Note that the areas covered in the articles "Mediterranean Basin" and "Middle East and the Caucasus" slightly overlap; for this synthesis, however, the complete territories of Turkey, Syria and Jordan are treated under the latter despite they also have a share of the Mediterranean Basin. Likewise, the Western Balkan countries Slovenia, Croatia, Bosnia and Herzegovina, Montenegro and North Macedonia in this table are fully counted under "Eastern Europe," despite they have significant areas in the Mediterranean Region. The numbers provided in this table are mostly rough estimates by the authors of the ten regional chapters and other experts because for the majority of presented facts there are no or no easily accessible hard data. The different grassland categories concerning origin and quality are defined in detail in the text. Fractions of original and maximum areas, respectively, refer roughly to the past 500 years, not to geological time scales. HNV grasslands = High Nature Value grasslands, i.e., natural grasslands in good state and semi-natural secondary grasslands combined. The threshold between the quality categories (a) and (b) is a biodiversity loss of 50%, both for natural and secondary grasslands.

^aAreas given here deviate from Boch et al. (2020) as these authors based their stats on FAO MODIS (FAO 2019), while we, in agreement with Dengler and Tischew (2018), use FAO CCI_LC (FAO, 2019), which corresponds better to other published stats (Smit et al., 2008; Eurostat, 2015).

^bAreas for Russia were taken from Reinecke et al. (2018).

Fig. 3 Examples of major grassland categories of the Palaeartic biogeographic realm (A–D: natural grasslands; E–H: semi-natural grasslands): (A) Steppe in Southern Ukraine; (B) Arctic-alpine grasslands form an extensive belt above the timberline in most Palaeartic mountains, here in the Swiss Alps; (C) coastal dune grassland in Sicily, Italy; (D) extrazonal steppic grasslands on steep slopes above the Rhone valley, Switzerland; (E) semi-dry basiphilous grassland in Transylvania, Romania, holding two small-scale world records of vascular plant species richness (see [Table 2](#)); (F) eutrophic, wet meadow, Slovenia; (G) extensive semi-natural grasslands, together with arable fields and hedgerows, are part of the traditional cultural landscapes in many parts of Europe, as here in Central Slovakia; (H) in East Asia, semi-natural grasslands are much less extensive, as here on Jeju Island, South Korea (photos by J. Dengler).

- (2) *Secondary grasslands* (occur in places where the natural vegetation is forest, shrubland, heathland or wetland; these grasslands developed under human land use like mowing, grazing, burning or abandoning arable fields)
- (2a) *Semi-natural grasslands* (secondary grasslands in which site conditions except for removing woody species remained more or less unaltered, e.g., no or very little artificial fertilization, no regular reseeding) (Fig. 3E–G).
- (2b) *Strongly intensified grasslands* (secondary grasslands in which the site conditions were altered strongly compared to the natural stage; in particular, with high land-use intensity to increase yield enabled through (artificial) fertilization).

In natural and secondary grasslands high levels of human impact generally reduces biodiversity and conservation value. However, initial, low-level intensification can even increase the biodiversity of certain grasslands, e.g., relatively species-poor extrazonal steppes in the Swiss inneralpine valleys have been transformed to species-rich meso-xeric grasslands by irrigation (in line with the loss of steppe-specialist species); also a very low level of fertilization or liming of very nutrient-poor and/or acidic secondary grasslands might increase species richness. However, any further land-use intensification (fertilization, higher stocking rates, more cuts per year, drainage, plowing and reseeding, removal of small-scale heterogeneity) will ultimately lead to a strong loss of biodiversity across taxonomic groups (Allan et al., 2014). To capture this process, we differentiate among the *natural grasslands* those “in good state” from those that are “strongly degraded” and in *secondary grasslands* the “semi-natural grasslands” from the “strongly intensified grasslands.” The natural grasslands in good state and the semi-natural secondary grasslands together are the so-called “High Nature Value” grasslands (HNV grasslands; Veen et al., 2009; Oppermann et al., 2012; Török and Dengler, 2018). As the loss of “nature value” is a gradual process, we reduced this concept and only distinguish High Nature Value grasslands from grasslands with low nature value. The threshold to distinguish between the two categories was the loss of 50% or more of the original biodiversity. The author teams of the chapters were asked to assess the situation in their particular region based on this definition. While we are not aware of any other definition that connects the concept of “High Nature Value” grasslands (or of the semi-natural grasslands within the secondary grasslands) with clear numbers of biodiversity loss, it is evident that some other publications used much stricter thresholds. When Bullock (2011) reports a loss of 97% of semi-natural grasslands in England and Wales (United Kingdom) since the mid-20th century, this evidently refers to a higher, yet undefined threshold. Definitions of semi-natural grasslands can also refer to other factors than biodiversity, e.g., in Estonia to the fact that a site has never been plowed (S. Rusina, Riga, pers. comm.). Instead of a dichotomy as we apply it here, other systems might use finer delimitations, e.g., Stevens et al. (2010) distinguished “unimproved,” “semi-improved,” and “improved” grasslands of which the first two approximately correspond to HNV grasslands in our sense. It is important to keep these different delimitations of HNV grasslands in mind when interpreting our Table 1.

Grasslands can also recover after cessation of arable fields, other human disturbance or the removal of afforestations. Actually this is a process that happened repeatedly in many regions of the Palaearctic (Poschlod, 2015; Brinkert et al., 2016; Kämpf et al., 2016) and nowadays is often assisted by restoration measures. For the sake of simplicity, we assign such recovered grasslands depending on their sites to either natural grasslands or secondary grasslands and depending on their quality to either HNV grasslands or non-HNV grasslands (to be kept in mind when interpreting Table 1).

Spatial Extent of Grasslands in the Palaearctic

Quantifying the extent of grasslands in the Palaearctic and its subunits is a major challenge, not only because of the different grassland definitions used in different sources (see above). Even when using the same FAO definition “area dominated by natural herbaceous plants (grasslands, prairies, steppes, and savannahs) with a cover of 10 per cent or more, irrespective of different human and/or animal activities, such as grazing or selective fire management. Woody plants (trees and/or shrubs) can be present, assuming their cover is less than 10 per cent,” values for individual countries vary sometimes strongly, depending on whether one refers to the one or the other remote-sensing based product provided by FAO (2019). Sometimes the grassland areas based on MODIS (Moderate-resolution imaging spectroradiometer) are much higher than those based on CCI_LC (Land Cover project of the European Space Agency Climate Change Initiative) (e.g., Turkmenistan: 93,722 MODIS vs. 27,083 km² CCI_LC), and sometimes the other way around (e.g., France: 48,791 km² MODIS vs. 121,408 CCI_LC); rarely both values are close together (e.g., Italy: 35,357 km² MODIS vs. 37,732 km² CCI_LC). Similar unexplained inconsistencies, albeit not as strong, were already recorded by Dengler and Tischew (2018) for Western and Northern European countries based on one FAO statistics and two other sources. We tried to use as far as possible national sources to overcome these unexplained inconsistencies, and, when such were not available, averaged the CCI_LC and MODIS-based values of FAO (2019).

According to our compilation (Table 1), there are about 10.0 million km² grasslands in the Palaearctic, corresponding to 18% of its territory. In our last, less detailed assessment (Török and Dengler, 2018), we had estimated 9.7 million km² and 22%, i.e., the first value is quite similar and the difference in the second can easily be explained by the fact that Török and Dengler (2018) excluded the Arab Peninsula, which hardly contains any grasslands but largely belongs to the Palaearctic biogeographic realm. Comparing these values with the FAO stats for the whole terrestrial surface of Earth (FAO, 2019: mean of MODIS and CCI_LC), it appears that the Palaearctic biogeographic realm comprises approx. 41% of the global grasslands (24.5 million km²), and thus more than any other biogeographic realm, while the fraction of grasslands here is slightly lower than the global average of 19%. The fractions of grasslands in the 13 regions distinguished range from 1% in the Sahara and Arab Peninsula to 77% in Mongolia (Table 1).

Overall, natural grasslands prevail with 76% vs. 24% secondary grasslands, but in the Europe, the Mediterranean Region, Korea and Japan secondary grasslands dominate, while natural ones often contribute < 10% (Table 1). Natural grasslands consist of 57% steppes, 32% arctic-alpine grasslands and 11% azonal and extrazonal grasslands (Table 1). Slightly less than three-fourths of their

original extent is still covered by grasslands, but in two regions the loss was particularly dramatic, Eastern Europe with 92% and Russia with 50% (Table 1). The remaining natural grasslands are predominantly (77%) considered as in good state. In those regions, where secondary grasslands nowadays prevail, they were even more widespread in the past, with area losses of typically 40%, but up to 75% in Northern Europe and the Baltic States (Table 1). More than two-thirds of the remaining secondary grasslands belong to our category “semi-natural grasslands,” i.e., they still contain at least half of their former biodiversity (Table 1). However, in three of the regions (Western Europe, Northern Europe and the Baltic States, Japan) meanwhile a clear majority of grasslands has been strongly intensified with severe negative impacts on their biodiversity (Table 1).

Biodiversity of Palaearctic Grasslands

Biodiversity Hotspots and Diversity of Taxa in General

Palaearctic grasslands have a significant share of the overall biodiversity of the Earth (for some examples, see Fig. 4). Among the 34 biodiversity hotspots recognized globally (among others defined by the presence of at least 1500 endemic vascular plant species; Mittermeier et al., 2004), six are located in the Palaearctic biogeographic realm: Mediterranean Basin, Caucasus, Irano-Anatolian, Mountains of Central Asia, Himalaya and Japan. All six comprise significant areas of natural and semi-natural grasslands which contribute largely to the overall biodiversity.

Grassland-dominated landscapes are rather young ecosystems in the geological history of the Earth. They originated and expanded in the Cenozoic (from ca. 40 million year), as the effect of the co-evolution of grasses and grazers (Retallack, 2001). In the past, Eurasian steppes supported large herds of wild ungulates such as the saiga antelope, the Przewalski's horse, the Asiatic wild ass, and the Bactrian camel. However, due to human activities most of these species have been extirpated in the wild or survive in only small herds in the Eastern Steppe (Visconti et al., 2018). Grazers typical for alpine grasslands, like ibex, chamois and wild sheep still exist in many mountain ranges in the Palaearctic realm. Other important consumers of plant biomass in grasslands that often play a role of ecosystems engineers in this Palaearctic grasslands are pikas and rodents (Wesche and Treiber, 2012), e.g., ground squirrels, marmots (Fig. 4H), voles, zokors, mole rats, hamsters, gerbils, and jerboas.

Grasslands are also very important for other groups of taxa. It was assessed that in Europe 29% (152 out of 526) of all bird species is associated with grasslands habitats (Nagy, 2014). Dry calcareous grasslands and steppes constitute habitat of 63% of Europe's butterfly species (274 out of 436, van Swaay et al., 2006; Fig. 4E), while in the case of *Orthoptera* (Fig. 4F) even 74% of the species occurring in Europe are dependent on open habitats, mostly grasslands (Hochkirch et al., 2016). European grassland areas also host many species of endemic terrestrial mollusks (Neubert et al., 2019). In the floras of vascular plants of Palaearctic countries, typically the grassland species are the largest group (e.g., Korneck et al., 1998, for Germany); and among the >6000 endemic vascular plant species of Europe those of grasslands (18.1%) constitute the second-largest group after rock-dwelling species (Hobohm and Bruchmann, 2009).

Exceptional Biodiversity at Small Spatial Scales

At small spatial scales (i.e., below 100 m²) Palaearctic grasslands can hold higher species diversity of plants even than tropical rain-forest (Wilson et al., 2012). Meso-xeric grasslands are the most species-rich grasslands (Fig. 3E) in the Palaearctic realm for most spatial scales, both regarding mean and maximum values (Fig. 5 and Table 2). Only at the smallest grain size, 1 cm², wet grasslands and mesic grasslands show higher means for vascular plants and total vegetation, i.e., including bryophyte and lichen species, respectively. Maximum richness values of vascular plants correspond specifically to meso-xeric grasslands in Eastern Europe for grain sizes larger than 0.1 m² (Table 2), with an outstanding value of 82 species in 1 m² (White Carpathians, Czech Republic), 98 in 10 m² (Transylvania, Romania; Fig. 3E) and 133 in 100 m² (White Carpathians, Czech Republic). Roleček et al. (2019) reported 106 vascular plant species in 10.89 m² (3.33 × 3.33 m) in the mentioned grassland from Transylvania and 119 vascular plant species in 16 m² from the Chernivtsi Mts. in Ukraine. For smaller grain sizes, meso-xeric grasslands still show the highest maximum richness for 10 cm², but in this case in Western Europe (Navarre, Spain), while a wooded meadow from the Baltic States and a wet grassland from Eastern Europe hold the maximum richness for 100 cm² (Estonia) and for 1 cm² (Poland), respectively (Table 2). Fig. 6 shows the differences across grain sizes and subregions of mean species richness of vascular plants of the richest vegetation type. Highest means change from Western and Northern Europe in the grain sizes up to 0.1 m² to Eastern Europe and Russia in the largest sizes (Fig. 6).

However, bryophytes and lichens exhibit different richness patterns than vascular plants, i.e., being more diverse in other grassland types (Fig. 7). Their fraction changes across the grain sizes, but rocky grasslands and sandy dry grasslands are usually the vegetation types with their highest proportion, with bryophytes normally more abundant in the former and lichens in the latter. Outstanding are the mean bryophyte richness values in wet grasslands (6.4) at 10 m² and Mediterranean grasslands (8.1) at 100 m², where they constitute 18.3% and 16.1% of the total richness, respectively (Fig. 7). As regards the maximum richness values, rocky grasslands from the Baltic islands (both in Sweden and Estonia) hold the bryophyte records for all grain sizes, as well as the lichen records for most grain sizes, except 1 cm² and 100 m², for which a sandy dry grassland and a meso-xeric grassland from Germany show the maximum values (Tables 3 and 4). However, Boch et al. (2016a) reported an outstanding value of 36 lichen species on 16 m² in a calcareous grassland in Germany (Baden-Württemberg; see dataset Boch et al., 2016b). It is worth to indicate that the fraction of bryophytes and lichens in total vegetation is changing even within particular vegetation types depending on the region.

Fig. 4 Examples of typical taxa of Palearctic grasslands: (A) *Stipa capillata*, a representative of one of the most-widespread drought-adapted tussock grass genera of the realm; (B) *Astragalus exscapus*, representing one of the most species-rich genera of Palearctic forbs and dwarf shrubs; (C) geophytes, like *Colchicum autumnale*, play a lesser role in only some grassland types; (D) *Abietinella abietina* is a widespread moss species of dry grasslands; (E) *Iphiclides podalirius* is a typical butterfly of dry grasslands throughout most of the Palearctic; (F) *Arcyptera fusca* is a herbivorous *Orthoptera* species grazing in dry grasslands; (G) family of Greylag geese (*Anser anser*) feeding in a wet grassland; (H) Alpine marmot (*Marmota marmota*), a grazer from the genus *Marmota*, which occurs with several medium-sized species in alpine grasslands as well as steppes (photos by J. Dengler).

Fig. 5 Vascular plant richness of Palearctic grasslands across grain sizes and 10 major grassland types. The values are means of all plots in each grain size across the Palearctic biogeographic realm that were contained in version 2.00 of the GrassPlot database (Dengler et al., 2018; Biurrun et al., 2019).

Table 2 Maximum richness of vascular plants across regions of the Palearctic realm, as considered in the Encyclopedia.

Area (m ²)	Western Europe	Northern Europe and Baltic States	Eastern Europe	Mediterranean Region	Middle East and Caucasus	Russia	Kazakhstan and Middle Asia	Mongolia	China	Japan	Place and grassland type of Palearctic maximum
0.0001	9	5	11	8	3	5	5	–	–	–	Poland: wet grassland
0.001	19	12	13	12	4	9	15	–	–	–	Spain: meso-xeric grassland
0.01	23	25^a	22	24	20	17	17	–	–	–	Estonia: meso-xeric grassland in a wooded meadow
0.1	34	35 ^b	43^c	37 ^b	34	28	28	–	–	–	Romania (shoot; Fig. 3E) and Czech Republic (rooted) ^c : meso-xeric grassland
1	53	49	82^c	48	48	52	37	11	59	58	Czech Republic: meso-xeric grassland
10	86	49 ^b	98	71	65	76 ^d	50	–	71 ^b	–	Romania: meso-xeric grassland (Fig. 3E)
100	110	70	133^c	99	85	109 ^d	67	34	76	–	Czech Republic: meso-xeric grassland

Richness is provided for the grain sizes from 1 cm² to 100 m². Data from version 2.00 of the GrassPlot database (Dengler et al., 2018; Biurrun et al., 2019), except for values marked by superscript numbers. Palearctic maximum richness values are indicated in bold.

^aChytrý et al. (2015).

^bRecords are for 10% smaller areas, i.e., 0.09 and 9 m², respectively.

^cWilson et al., 2012.

^dUnpublished data provided by M. Chytrý.

Fig. 6 Mean vascular plant richness of meso-xeric grasslands across grain sizes and Palearctic regions. Note that the Mediterranean Region and Middle East and Caucasus were joined to get sufficient number of plots in some grain sizes. Japan and Korea, Kazakhstan and Middle Asia, China and Mongolia are not included, because there are not data of meso-xeric grasslands at any grain size, or only at one.

Fig. 7 Species richness and taxonomic composition of the vegetation of 10 major grassland types. The values are means of all the 10-m² plots across the Palearctic biogeographic realm that were contained in version 2.00 of the GrassPlot database (Dengler et al., 2018; Biurrun et al., 2019). Mean richness values of bryophytes and lichens are calculated only for those plots in which they were recorded. Note that the relatively high fraction of non-vascular plants in saline grasslands is due to the fact that non-vascular plants were recorded only in a small subset of these that is not typical for saline grasslands in general.

As an example, Fig. 8 (left) shows the fraction of vascular plants, bryophytes and lichens of meso-xeric grasslands across subregions at 10 m². Meso-xeric grasslands from northern Europe hold the highest fraction of both bryophytes and lichens, as well as the highest mean richness values of these taxonomic groups. This pattern is conserved in rocky grasslands, which hold the highest fraction of bryophytes and lichens at the level of the Palearctic realm. Once again, Fig. 8 (right) shows that at 10 m² rocky grasslands from Northern Europe hold by far the highest fraction and highest mean values of both bryophytes and lichens, followed by rocky grasslands from Western Europe.

The species richness of other taxa than vascular plants are only rarely reported in the literature. We therefore analyzed data of the Biodiversity Exploratories, a large-scale and long-term functional biodiversity research project (www.biodiversity-exploratories.de/1/home/) where many taxa were sampled on the same plots in 150 differently managed grasslands in three regions of Germany and used for synthesis analyses (e.g., Allan et al., 2014; Blüthgen et al., 2016; Gossner et al., 2016; Soliveres et al., 2016a,b). In plots with a size of 50 × 50 m, on average 3.5 bird species (max. 19; for methodological details see Wells et al., 2011) and 3 bat species (max. 10; years

Table 3 Maximum richness of bryophytes across regions of the Palaearctic realm, as considered in the Encyclopedia.

Area (m ²)	Western Europe	Northern Europe and Baltic States	Eastern Europe	Mediterranean Region	Middle East and Caucasus	Russia	Kazakhstan and Middle Asia	China	Place and grassland type of Palaearctic maximum
0.0001	4	5	4	5	1	3	1	–	Estonia: rocky grassland and Italy: Mediterranean grassland
0.001	6	9^a	7	8	1	4	2	–	Estonia: rocky grassland
0.01	7	18	10	9	1	5	2	–	Sweden: rocky grassland
0.1	10	24^a	10	10	2	9	2	–	Sweden: rocky grassland
1	13	31	11	18	2	11	3	–	Sweden: rocky grassland
10	27	40^a	18	19	2	13 ^a	7	–	Sweden: rocky grassland
100	23	38	17	23	3	19	9	2	Estonia: rocky grassland

Richness is provided for the grain sizes from 1 cm² to 100 m². Data from version 2.00 of the GrassPlot database (Dengler et al., 2018; Biurrun et al., 2019). Palaearctic maximum richness values are indicated in bold. For Mongolia and Japan, GrassPlot 2.00 does not contain plots with records of bryophytes.

^aRecords are for 10% smaller areas, i.e., 0.0009, 0.09 and 9 m², respectively.

Table 4 Maximum richness of lichens across regions of the Palaearctic realm, as considered in the Encyclopedia.

Area (m ²)	Western Europe	Northern Europe and Baltic States	Eastern Europe	Mediterranean Region	Russia	China	Place and grassland type of Palaearctic maximum
0.0001	4	2	2	1	3	–	Germany: sandy grassland
0.001	4^a	6^a	2	1	2	–	Sweden: rocky grassland
0.01	7	8	3	3	6	–	Sweden: rocky grassland
0.1	10 ^a	15^a	4	5	8	–	Sweden: rocky grassland
1	11	21	8	5	17	–	Sweden: rocky grassland
10	16 ^a	24^a	12	10 ^a	20	–	Sweden: rocky grassland
100	31	25	15	15	28	3	Germany: meso-xeric grassland

Richness is provided for the grain sizes from 1 cm² to 100 m². Data from version 2.00 of the GrassPlot database (Dengler et al., 2018; Biurrun et al., 2019). Palaearctic maximum richness values are indicated in bold. For Middle East and Caucasus, Kazakhstan and Middle Asia, Mongolia and Japan, GrassPlot 2.00 does not contain plots with records of lichens.

^aRecords are for 10% smaller areas, i.e., 0.0009, 0.09 and 9 m², respectively.

2008–2012; for methodological details see Heim et al., 2015; Treitler et al., 2016) occurred. Sweep netting along transects in these plots (Simons et al., 2014, 2015, 2016; Neff et al., 2019), revealed on average 19.8 *Hemiptera* (max. 34) and 1.6 *Orthoptera* species (max. 5). As sweep netting largely excludes most ground-dwelling species, e.g., *Araneae* species (spiders) and *Coleoptera* species such as most carabid beetles, the sweep netting approach was combined with pitfall trapping in a subset of 27 plots (Lange et al., 2011; Allan et al., 2014). This resulted in 7.5 and 8.5 times higher mean numbers of *Coleoptera* species (mean 13 vs. 98.1, max. 34 vs. 153 species) and *Araneae* species (mean 3.6 vs. 30.6, max. 11 vs. 56 species), respectively, than the pure sweep-netting approach.

Factors Influencing Alpha Diversity of Grasslands

As in all other biogeographic realms and biomes, biodiversity of Palaearctic grasslands is shaped simultaneously by many environmental factors. Therefore it is impossible to point out only one or two major predictors of species diversity. Moreover, the main drivers of biodiversity can be properly indicated only for a given spatial scale (Huston, 1999) and for different taxonomic groups the observed patterns can be opposite (Mateo et al., 2016).

Coarse-scale diversity patterns of plants in Palaearctic grasslands are determined mostly by climate and geological history (Antonelli et al., 2018). With regard to climatic factors, evapotranspiration as a climatic parameter that combines some of the effects of precipitation, temperature, solar radiation, and other factors in a single value seems to be the most important (Huston, 1999), but this still needs to be confirmed for Palaearctic grasslands. The geological history, like formation of mountain ranges, past climate changes and glaciations greatly impacted the current distribution of species. Exceptionally diverse regions, rich in endemic plant species, usually occur in mountainous regions, former glacial refugia, and especially in places with calcareous bedrock (Smyčka et al., 2017; Noroozi et al., 2018; Večeřa et al., 2019).

In a more local scale, plant diversity in grasslands is determined e.g., by primary productivity, fertility and pH of soil, as well as management or natural disturbance regime. In general, primary productivity influences plant species richness according to a unimodal relationship (Fraser et al., 2015). Productivity in grasslands is mostly determined by climate (precipitation, temperature and length of growing season) in case of natural, climatogenic grasslands, while in semi-natural grasslands it also strongly depends on soil fertility. Palpurina et al. (2019) found that the type of nutrient limitation can affect the plant species richness-productivity

Fig. 8 Species richness and taxonomic composition of the meso-xeric grasslands (*left*) and rocky grasslands (*right*) across Palearctic subregions. Displayed are means of all 10-m² plots contained in version 2.00 of the GrassPlot database (Dengler et al., 2018; Biurrun et al., 2019) in which all three taxonomic groups were recorded. Note that Mediterranean and Middle East & Caucasus were joined for meso-xeric grasslands to get a sufficient number of plots. Japan and Korea, Kazakhstan and Middle Asia, China and Mongolia are not included because of lack of data.

relationship in Palearctic dry grasslands: species richness increased more steeply and peaked higher under elevated productivity levels at nitrogen and phosphorus co-limited sites. Similarly to productivity, a hump-shaped relationship was found for soil pH and plant diversity at the regional scale, with highest richness in neutral or slightly basic pH, but in drier conditions this relationship became negative or was not significant (Palpurina et al., 2017).

Management is a particularly important driver of species richness in semi-natural grasslands, as abandonment usually is followed by secondary succession towards shrubland or forest communities. Traditional, extensive management, like grazing or mowing, usually supports high diversity of grasslands, while intensification through excessive application of fertilizers, frequent mowing, sowing of highly productive species of grasses and/or legumes, and also too intensive grazing often lead to biodiversity decline (e.g., Socher et al., 2012; Török et al., 2016; Boch et al., 2018). It should be noted that in case of natural grasslands, the natural factors shaping their diversity quite often are disrupted by human activities, thus their biodiversity can also decline if there is no active conservation measure, e.g., replacing grazing by wild animals (that are locally extinct) or natural fires (Havrylenko, 2011).

Species-Area Relationships and Beta Diversity

Extensive multi-scale sampling conducted on Palaearctic grasslands in recent years with application of standardized methodology (Dengler et al., 2016) and other data stored in the GrassPlot database (Dengler et al., 2018; Biurrun et al., 2019) revealed other interesting macroecological patterns. Analyses of data coming from 2057 nested plot series in Palaearctic grasslands (with at least seven grain sizes varying from 1 cm² to 1024 m²) confirmed that the power function $S = c A^z$ (where S is the species number, A represents area and c and z are fitted parameters of the function) describes species-area relationships (SARs) in Palaearctic grasslands best (Dengler et al., 2020a).

Moreover, the exponent z of the power function, which describes how fast species richness increases with increasing area, can give valuable ecological information, i.e., on the fine-scale beta diversity. Such beta diversity (called multiplicative beta diversity; Jurasinski et al., 2009) is calculated according to the formula $z = \log_{10}(S_\gamma/S_\alpha)/\log_{10}(A_\gamma/A_\alpha)$, where S_i is the species richness and A_i the area at the α - and γ -level, respectively. Fine-scale beta-diversity is useful in comparing the rate of spatial species turnover between different ecological situations. Analyses performed on 4546 nested plot series in Palaearctic grasslands showed that taxonomic groups significantly differ in this respect with bryophytes having the lowest, and lichens the highest beta diversity (Dengler et al., unpublished). Fine-scale beta diversity of Palaearctic grasslands can be controlled by environmental factors, that can have positive impact like habitat heterogeneity (Polyakova et al., 2016; Dengler et al., unpublished), negative impacts like heat load (proxy of the drought stress) and productivity (Chiarucci et al., 2006; Turtureanu et al., 2014), or unimodal effect as in annual precipitation (Polyakova et al., 2016; Dengler et al., unpublished).

Threats and Conservation

Overall Threat Assessment

In the Palaearctic region, grasslands are important habitats for many species of global conservation concern (Habel et al., 2013; Török et al., 2016; Török and Dengler, 2018). These type of terrestrial habitats are among the most intensively and negatively human-impacted ones, characterized by a strong declining trend in habitat extent (see Table 1) and intactness as well as species diversity and abundance since the second half of the 20th century (Visconti et al., 2018). Because of that, a high proportion of grassland types (e.g., Janssen et al., 2016) and associated species are endangered today (Visconti et al., 2018). Alarming losses of species abundances in a rather short time period and the homogenization of species communities by supporting generalist species at the expense of habitat specialists were reported for well-monitored taxa such as farmland birds (57% population decrease) and grassland butterflies (45% population decrease) in Western and Central Europe (Visconti et al., 2018). Mollusk abundance and diversity has also declined with grassland intensification or conversion to arable land (Neubert et al., 2019).

In Table 5, we summarize the major threats to grassland biodiversity in the 10 regions of the Palaearctic biogeographic realm, separated in drivers of biodiversity loss during the past decade and projected change of the impact of these drivers in the next decade. The table was mainly based on expert assessments by the author teams of the ten regional chapters, combined with the findings of the IPBES regional assessment report on biodiversity and ecosystem services for Asia and the Pacific (Karki et al., 2018) as well as for Europe and Central Asia (Rounsevell et al., 2018). We used a comprehensive classification of drivers with 16 threat categories, arranged in six main groups, updated from Török and Dengler (2018).

Generally, the drivers of the category “changes in grassland management” were considered as the most negative ones (Table 5). While in Mongolia and China, overgrazing is the major cause of biodiversity loss, in the more oceanic areas (with prevailing secondary grasslands), the “twin threats” of abandonment/underuse and other forms of intensification than overgrazing have this role (Table 5). Habitat loss generally is the second most important driver of biodiversity loss of grasslands, with built-up areas, arable fields and afforestation being seen as similarly important, but with regional differences (Table 5). Up to now, on average 28% of the natural grasslands and 38% of the secondary grasslands got completely lost that way, but regionally losses are much more dramatic, with up to 92% for natural grasslands (Eastern Europe) and 75% for secondary grasslands (Northern Europe and Baltic States). Altered site conditions in general were of only moderate impact on biodiversity currently, with the exception of eutrophication, which is one of the most important drivers in Western Europe, and to a lesser extent in Northern Europe and the Baltic States. In Europe formerly also drainage of wet grasslands was a major course of biodiversity loss (Wesche et al., 2009), but the large-scale drainages are largely history, while nowadays locally even re-wetting projects are performed. The three other driver groups, climate change, invasive species and direct impact of humans and their infrastructure were generally considered of lesser importance, but also with some regional differences (Table 5). When projecting the current trends into the future, the regional author teams largely assumed that the same drivers that cause biodiversity loss today will continue to do so at a similar level in the next 10 years (Table 5). The only two drivers where a significant proportion of regional author teams predicts stronger negative impact in the future are climate change and invasive species.

Individual Threat Factors

Land-use change (including changes from intensification to the complete abandonment) was identified as the major driver of habitat degradation, large-scale biodiversity loss and homogenization of species assemblages by the IPBES assessment (Visconti et al., 2018), consistent with our own assessment (Table 5). On the one hand, intensification of land use aims to increase the productivity of grasslands; it is mostly achieved with the addition of organic or inorganic fertilizers and the broadcast of high-

Table 5 Overview of the main drivers of grassland biodiversity loss, their current impact (i.e., rate of biodiversity loss caused by them 2010–2019) and its anticipated future change (i.e., change in the rate of biodiversity loss in 2020–2029 compared to the situation in 2010–2019).

"Current impact" is given on a five-step ordinal scale (none—low—medium—high—very high), while "Future change" was assessed on a three-step ordinal scale ("decrease"—"± constant"—"increase"), where "± constant" means that the biodiversity loss due to this driver is expected to continue in the next decade at the same level as in the previous decade ($\pm 10\%$). Please note that in order to get an assessment of the expected impact during the next decade, both columns have to be combined: for example, if the current impact is "medium" and the future change is predicted to be an "increase," the future impact would be "high" (or even "very high"). Likewise, even if the importance of a driver is predicted to decrease, it will in most cases still cause additional biodiversity loss during the next decade. "NA" = not assessed.

^aThis includes area loss due to open-cast mines and water dams for energy production.

^bOvergrazing is not widespread but in some places it is an important driver of biodiversity loss.

^cThis includes high cutting frequency, pesticide application, re-seeding and homogenization of grasslands/removal of heterogeneity.

^dThis refers to direct fertilization, spill-over from neighboring fields and airborne nitrogen input.

^eThis refers both to drainage and irrigation.

^fExcept for the sprawling city of Almaty and its satellite towns ("high").

^gIn the absence of war, military training areas had in the past even a positive or very positive effect on grassland biodiversity, but during the past decade the diversity in these areas remained $\pm$ constant.

^hAbandonment and underuse "high" in steppes of Kazakhstan but "low" in remaining regions.

ⁱOvergrazing by livestock is not widespread but biodiversity loss by wild deer browsing will increase in semi-natural grasslands.

^jHay making ("low"/"± constant"), use of pesticides ("none"/"± constant").

^kPaddy consolidation and increased sown pastures.

^lGenerally "none" to "low," but "high" in some meadows.

^m± Constant because of recent dam reservoir constructions in Pamir-Altay and surroundings.

ⁿGenerally "none" to "low," but "high" in oceanic islands.

^oTraining grounds for the Japan Self-Defense Forces have maintained semi-natural grassland biodiversity.

^pSki slope grasslands have maintained semi-natural grassland biodiversity whereas off-road vehicle recreation degrades coastal and riparian grasslands.

^qHunting pressure on wildlife will decrease due to aging of hunters.

^rElectrocution ("high"/"± constant") and wind farm collisions ("low"/"increase," but "low"/"± constant" in Kirgystan and Tajikistan).

^sElectrocution ("moderate"/"± constant"), wind farm collisions ("none"/"± constant").

^tWind farm construction has negative effects on coastal grassland biodiversity in the northern part of the country.

^uWild fires variable by region: "very high"/"increase" in steppes of Kazakhstan to "low"/"± constant" in remaining regions.

production grass and forb cultivars. Productive grasslands are mown more frequently or grazed at higher stocking densities compared to extensively managed grasslands (Blüthgen et al., 2012). Intensive management promotes a few mowing-tolerant species (e.g., Socher et al., 2012) or leads to diversity loss due to overgrazing (Török et al., 2016). The conversion of a large proportion of semi-natural to intensified grasslands caused a large-scale landscape simplification and homogenization, especially in Western and Central Europe (Visconti et al., 2018). This is resulting in a multi-trophic homogenization of grassland communities, the loss of specialist species and ecosystem multifunctionality (Gossner et al., 2016; Soliveres et al., 2016a,b). On the other hand, the cessation of grassland management in general leads to litter accumulation, increased competition by community generalists and woody encroachment on the long-run. In the future, woodland increase and further grassland declines are particularly projected for Western and Central Europe (Harrison et al., 2018). The cessation of traditional land use is associated also with the loss of indigenous and local knowledge and practices (Elbakidze et al., 2018). However, effects of abandonment might differ among vegetation types, regions and taxa (Kämpf et al., 2016; Valkó et al., 2018). There is evidence for particularly strong negative effect of the cessation of grassland management on the biodiversity in semi-natural grassland systems of temperate regions (Dengler et al., 2014; Rotherham, 2015) and mountain areas (MacDonald et al., 2000; Valkó et al., 2012; Boch et al., 2019). This is in accordance with our evaluation, as the threat group “Changes in grassland management” was identified as the most negative one (Table 5). In addition, abandonment and underuse was identified as an important driver of biodiversity loss in Europe (Western Europe, Northern Europe and Baltic States, and Eastern Europe), but also in the Middle East and Caucasus, Russia or Japan. Also the negative impacts of abandonment were assessed to remain constant or even increase in some regions (Table 5). Another important driver was intensification of land use in form of overgrazing (Mongolia and China) and other forms of intensification mostly for hay making (Western Europe, Northern Europe and the Baltic States and Japan; Table 5).

Habitat loss in the form of conversion to arable land, afforestation, mining and energy production or urbanization (settlements and other infrastructure) was assessed to have a high impact in Western Europe (conversion to arable land) and in the Middle East and the Caucasus (afforestation). In most regions, however, its current impact was assessed from low to medium with a remaining trend for the future. Abandonment of crop production in marginal or low-production cropland areas promotes the recovery of landscape-scale biodiversity, as on the abandoned areas in case of proper sources of propagules available in the landscape grasslands spontaneously regenerates. This type of large-scale recovery was typical for Central Asian steppes after the dissolution of the USSR (Brinkert et al., 2016; Kämpf et al., 2016). This recovery was further associated with increased ecosystem functioning because of increased soil carbon sequestration (Kurganova et al., 2015). In contrast, in Western Europe the reuse of fallow lands is typical – which also resulted in the conversion of spontaneously recovered grasslands. The eutrophication was identified as an important threat for grassland biodiversity in Western Europe (by fertilizer application, aerial nitrogen deposition and run-on of fertilizers from neighboring fields), but having only low impact in most of the other regions. Altered water regime was assessed having currently no to medium impact (but had strong negative impact in some regions in the past).

Negative effects of invasive alien species encroachment include suppression of native species, gene drift, homogenization of species assemblages and modifications of habitats and ecosystem functions. Moreover, invasive alien species might have negative economic and human health consequences (Nentwig et al., 2016, 2018; Elbakidze et al., 2018). Western European countries have the highest numbers of invasive alien species in the Palearctic realm due to trade and colonial histories, the invasion rates continuously increasing in all environments, taxonomic groups (except mammals), and subregions and there is no sign of reversing or slowing down this trend. However, there are data limitations in large parts of the region outside Europe (Karki et al., 2018; Rounsevell et al., 2018). Although the invasion threat during the 21st century is expected to be medium to very high in most parts of Europe and Central Asia (except Northern regions), the negative impact of invasive alien species on Palearctic grasslands so far has been evaluated as low to moderate (Török and Dengler, 2018). In the current assessment a medium impact of invasive species were assessed in Europe (excluding Northern Europe and Baltic States where it was low) and Russia, but was low and even negligible (Mongolia) in other regions. This might be because of the low number of high-impact invasive aliens that are actually associated with grasslands (see Nentwig et al., 2018). However, effects of invasions are expected to increase in future (Table 5) and might be particularly accelerated by climate change, but the outcome will largely depend on effective management and policy measures (Elbakidze et al., 2018).

Climate change is expected to come along with increased temperatures, reduced precipitation and increased numbers of extreme weather events in large parts of the Palearctic realm. Projected habitat changes can lead to transitions in species composition and diversity loss. While desertification risk is particularly high in Asian steppe regions (Faridah-Hanum et al., 2018; Visconti et al., 2018), mountain and northern grasslands are affected by northwards and upwards shifting thermophilous species, which can cause a decline of cold-adapted, high-elevation species (Gottfried et al., 2012; Steinbauer et al., 2018). Moreover, climate change might accelerate the negative effects of other major drivers of biodiversity loss (Faridah-Hanum et al., 2018; Visconti et al., 2018). In the present assessment, we found the current impact of climate change from low to medium but in most regions an increasing impact was assumed for the future. With climate change spontaneous wildfires and arsons will likely increase, which can have high impact on the biodiversity (we assessed its current impact to be high in Russia).

Further direct human impacts such as military and armed conflicts vary among the regions: In absence of war, for example in Western Europe, Northern Europe and the Baltic States or Japan, military training areas are associated with extensive land use and low accessibility, which is highly promoting grassland diversity. In contrast, grassland biodiversity is threatened by armed conflicts in regions such as Eastern part of Ukraine, the Middle East and Central Asia (Török and Dengler, 2018, Table 5). In most parts of Asia and the Middle East and Caucasus the collecting of wild plants and hunting was assessed to have medium impact on grassland biodiversity. Impact of recreation activities, wildlife loss due to electrocution and wildfires (for the latter two in exception of Russia where they were assessed as medium and high, respectively) was assessed to be low or not present in most regions.

Conservation and Restoration of Grasslands

In the last decades, much attention has been given to the conservation and restoration of biodiversity in natural and semi natural habitats, including grasslands of the Palaearctic realm and elsewhere (Brudvig, 2011; Török et al., 2018). Conservation authorities seek cost-effective ways to restore and sustain grassland biodiversity by considering theoretical findings on dispersal, species pool, community assembly rules and biodiversity patterns (Laughlin, 2014; Török and Helm, 2017). In the last years, various conservation efforts to monitor, maintain and promote grassland extent and diversity were made. This includes large national biodiversity monitoring programs (e.g., Bergamini et al., 2019), subsidies to farmers and restoration efforts. In Europe, there are many landscape-scale grassland restoration programs funded by the EU. Browsing the LIFE program database searching for themes of “Habitats-Grasslands” with the keyword “restoration measure” retained 101 projects in the 1993–2017 timeframe (European Union, 1995–2019). However, a large proportion of subsidies within the EU common agricultural policy (CAP) is still misleading as they often promote productive grasslands and do not conserve HNV grasslands and their diversity (Sutcliffe et al., 2015). A rethinking and the development of appropriate tools to reverse negative trends are urgently needed. This aspect is of particular importance in current nature conservation planning, as the European Union’s CAP assigns outstanding importance to permanent grassland for species protection. Permanent grassland is an agricultural term that is generally defined as “land used by sowing or self-seeding for the cultivation of grasses or other forage plants and not used as arable land for at least five years” (Bundesamt für Naturschutz, 2014). However, the basic EU guidelines on the promotion and conservation of permanent grasslands do not only lack specific management recommendations, but do not distinguish between extensively and intensively managed permanent grasslands with regard to their impact on environmental and biodiversity protection, which to our opinion also should be considered in the revision of the CAP for the next funding period (see Péter et al., 2014, 2019). However, at a specific level there are various management-related instruments for achieving environmental objectives in the common European agricultural policy (e.g., agri-environmental and climate measures, organic farming and animal welfare measures; see Bundesministerium für Ernährung und Landwirtschaft, 2015).

Glossary

Acidophilous Thriving in an acidic environment.

Basiphilous Thriving in an alkaline environment.

Biocoenosis Biotic community.

Chamaephyte Woody plant bearing its dormant vegetative buds up to 30 cm above the ground level.

Geliturbation Frost-driven movements of unconsolidated, superficial material.

Hemicryptophyte Herbaceous perennial plant bearing its dormant vegetative at the ground level.

Oligotrophic Thriving in an nutrient-poor environment.

Phytosociology Classification of plant communities based on compositional data.

Thermoxerophilous Thriving in a warm and dry environment.

Therophyte Herbaceous annual plants, surviving the adverse season in the form of seeds.

Abstract

The Mediterranean Region extends to the 1.6% of the world's land surface and more than the half of the Mediterranean-type ecosystems of the world. The remarkable species richness in the Mediterranean Region mainly originates from an exceptional habitat diversity and the presence of several natural barriers facilitating the segregation and differentiation of local taxa and biocoenoses. In this article, we deal with the habitats characterized by grasslands and shrublands that clearly show the adaptations to what could be called "the Mediterranean syndrome", i.e., the intrazonal Mediterranean grasslands and shrublands (MG&S). The main driving forces of the adaptive radiation and high biodiversity that characterize the MG&S are geographical segregation and appearance of new lands, climatic variability, substrate heterogeneity, species-specific plant-animal interactions and short generation times. MG&S are of paramount importance for delivering a wide array of ecosystem services. Apart from their importance for the maintenance of biodiversity, they play a major role in providing high quality forage for both livestock and wild animals; they support communities of insects with major roles in the ecosystem services of control and pollination; they sustain apiculture, and contribute to the prevention of erosion processes and maintenance of the water cycle; they buffer the negative impacts from fertilizers and pesticides and display highly significant aesthetic and recreational values. However, major threats to the provision of ecosystem services mostly originate from climate change, and recent land use changes (such as: "coastalization," unbalanced grazing activities and abandonment of traditional

practices). To mitigate the adverse effects of land use changes, the management of MG&S may be based on four principles; (a) ecosystem sustainability, (b) natural regeneration, (c) multifunctionality, and (d) protection.

Delimitation and Physiogeography

The Mediterranean Region consists of thousands of differently sized islands and peninsulas, surrounded by the Mediterranean sea. The most important ecological feature of the Mediterranean Region is a very peculiar climate: despite its proximity to the sea, the warmest season is also the driest. This requires from terrestrial sessile or low vagile organisms several morphological and physiological adaptations to tolerate or to avoid the summer drought stress. On the other hand, winter is the rainiest season and the relatively mild temperatures of wintertime make the Mediterranean Region “wintergreen,” at least close to the sea, because the Mediterranean mountains can impose a severe winter cold stress to their living organisms (Guarino, 2001).

The Mediterranean Region extends on 2,073,806 km² (Olson et al., 2001), i.e., 1.6% of the world’s land surface and more than the half of the Mediterranean-type ecosystems of the world (Fig. 1; Esler et al., 2018). The distribution ranges of the genus *Cistus*, as well as that of species like *Quercus ilex* and *Olea europaea*, outline quite well the boundaries of the Mediterranean Region.

The biological diversity of the Mediterranean Region is very high, currently estimated in 400,000–600,000 different species of living organisms, sea included (Hofrichter, 2001). Among them, about 25,000 are vascular plants, half of which are endemic to the whole Region or to smaller parts of it. Additionally, the fauna of the Mediterranean biogeographical region shows a great variety; 75% of the total European insect fauna are found here (Balletto and Casale, 1991). Similarly, levels of endemism are high for most groups of insects (Blondel and Aronson, 1999).

In spite of the high rate of endemism at the genus and species level in the vascular flora of the Mediterranean Region, high-rank endemics are rare (no endemic families, with the exception of the monotypic carnivorous *Drosophyllaceae*; few endemic subfamilies, such as *Aphyllanthoideae*). This testifies the relatively short evolutionary history of the Mediterranean flora and fauna (Cowling et al., 1996; Rundel et al., 2016). As we will see, the beginning of the speciation processes featuring the present-day Mediterranean biodiversity can be fixed in the mid-Pliocene.

The remarkable species richness in the Mediterranean Region is mainly caused by an exceptional habitat diversity and to the occurrence of several natural barriers facilitating the segregation and differentiation of local taxa and biocoenoses. The landscape heterogeneity and the natural fragmentation of habitats did not only have a direct influence on the local biodiversity, but also on the human land use and cultural diversity. In the last 12,000 years, human practices contributed to increase the patchiness of the Mediterranean landscapes and favored the establishment of grasslands and shrublands to the detriment of pristine forests. According to FAOstat (2014), grasslands cover 21.3% and shrublands 24.0% of the Mediterranean Region. (CCI LC data set limited to the Mediterranean part of the following countries: Albania, Algeria, Bosnia and Hercegovina, Croatia, Cyprus, France, Gibraltar, Greece, Holy See, Italy, Israel, Lebanon, Malta, Monaco, Montenegro, Morocco, Palestine, Portugal, San Marino, Slovenia, Spain, Spain, Tunisia.)

The topographic diversity may exasperate or alleviate the main climatic driver of the Mediterranean ecosystems, which is summer aridity. Therefore, in azonal vegetation under generically mesic or wet conditions, it often happens that the microclimatic and edaphic conditions favor a vegetation that is structurally and floristically quite similar to that of the European temperate ecosystems. In this article, we will only deal with the habitats characterized by grasslands and shrublands that clearly show the adaptations to

Fig. 1 Approximate delimitation of the Mediterranean Region covered by this article. Adapted from Olson, D. M., Dinerstein, E., Wikramayake, E. D., et al. (2001). Terrestrial ecoregions of the world: A new map of life on earth. *BioScience* 51, 933–938.

Table 1 Synopsis of the main adaptive responses to the environmental stresses of the plant species of MG&S.

<i>Environmental stress</i>	<i>Functional trait</i>	<i>Functional consequence</i>
Winter cold	Winter dormancy	Tolerance to low temperatures
	Low stature of plants	Reduced physical stress and frost damage
	Persistent dead leaves	Seasonal isolation of the buds
Summer drought	Epidermal trichomes, waxes, thick cuticle	Reduced evapotranspiration
	Sunken stomata, conduplicate leaves	Increased boundary layer resistance
	Reduced leaf area	Reduced water loss
	Summer loss of the leaves	Reduced evapotranspiration
	Aromatic oils in the stomatal chambers	Decreased evapotranspiration
	Thorny, hairy pulvinate architecture	Effective captation of the air moisture
	High root/shoot ratio	Increased absorptive area
	Deep rooting	Access to perennial water
	Dimorphic root system	Access to dew and deep water
	Poikilohydry	Tolerance to extreme drought
Summer heat	Therophytic/Geophytic habit	Avoidance of extreme drought
	Rapid root growth of seedlings	Adequate water supply
	Reduced or dissected leaves	Reduced heat loading
	Open canopy architecture	Sensible heat removal
	Epidermal trichomes, waxes, thick cuticle	Increased reflectance
Wildfires	Succulence	Increased thermic inertia
	Precocity/serotiny	Fire avoidance
	Myrmecochochory	Maintenance of viable populations
	Persistent, soil-stored seeds	Maintenance of viable populations
	Resprouting rootstocks	Vigorous post-fire regeneration
Nutrient limitation	Geophytic habit	Rapid re-establishment
	Secondary flammable compounds	Limited fire damage
	Bacterial symbioses	Facilitation of nutrient uptake
	Fungal symbioses	Facilitation of nutrient uptake
	Pulvinate architecture	More effective retention of the organic matter
	Slow growth at maturity	Reduced nutrient requirements
	Cluster roots	Increased exchange surface
	Big rootstocks	Nutrient sequestration
	Cumulative set of persistent seeds	Slow build-up of seed store
	Entomogamy	Optimization of resources
Predation	Spines and/or secondary aromatic/toxic compounds	Unpalatability
	Sclerophylly	Little nutrient content for herbivores
	Anemochory	Minimization of predator resource base
	Low seed set	Minimization of predator resource base
	Prolific seed set	Predator satiation
Wind	Myrmecochochory	Avoidance of post-fire predation
	Reduced/slender leaves and/or stems	Reduced physical resistance and damage
	Low stature of plants	Reduced mechanical stress
Ionic imbalance/toxicity	Anemochory	Optimal dispersal strategy
	Ion exclusion at the surface of the roots	Tolerance of salinity
	Cytoplasmatic compartmentalization	Tolerance of salinity
Physiological drought	Salt extrusion through specialized glands or bladders	Tolerance of salinity
	High osmotic pressure in the tissues	Adequate water supply

From Guarino, R. (2006). On the origin and evolution of the Mediterranean dry grasslands. *Berichte der Reinhold Tüxen Gesellschaft* **18**, 195–206; Guarino, R., Giusso del Galdo, G. and Pignatti, S. (2006). The Mediterranean dwarf shrubs: Origin and adaptive radiation. *Annali di Botanica N. S.* **5**, 93–101.

what could be called “the Mediterranean syndrome”, i.e., the intrazonal Mediterranean grasslands and shrublands (MG&S). Relevant physiognomic, adaptive and floristic differences are featuring in these vegetation types. The main structural and functional traits of the plants growing in the MG&S are reported in **Table 1** and will be summarized in the following sections, in which the taxonomic nomenclature follows Euro + Med PlantBase (accessed in September 2019, www.emplantbase.org) and the syntaxonomy of vegetation types follows the EuroVegChecklist (Mucina et al., 2016).

Typology of Mediterranean Dry Grasslands

In the Mediterranean Region, three main structural and functional types of zonal dry grasslands can be recognized (Guarino, 2006), i.e., those dominated by large caespitose hemicryptophytes (wintergreen perennial dry grasslands), those dominated by

Fig. 2 Characteristic Mediterranean grasslands and shrublands; (A) Dehesa (Córdoba, Spain), (B) dry perennial grasslands of *Celtica gigantea* (*Stipo giganteae-Agrostietea castellanae*) (Toledo, Spain), (C) dwarf shrublands of *Cistus clusii* and *Rosmarinus officinalis* (*Ononido-Rosmarinetea*) (Cuenca, Spain), (D) grasslands of *Agrostis castellana* (vallicares), (E) shrublands (scrubs) of *Thymus vulgaris* (*Ononido-Rosmarinetea*), (F) shrublands (scrubs) of *Lavandula pedunculata* and *Thymus mastichina* (*Cisto-Lavanduletea stoechadis*) Toledo (Spain). Photos by María Pilar Rodríguez Rojo.

thermoxerophilous therophytes (wintergreen ephemeral dry grasslands), those dominated by relatively small chamaephytes and hemicryptophytes, occurring at higher elevations but below the timberline (summergreen perennial dry grasslands) (Figs. 2 and 3).

Wintergreen Perennial Dry Grasslands

Vegetation widely distributed in the most xeric habitats of the Mediterranean Region, under a rather long (usually over 3 months) summer drought period (San Miguel et al., 2016). With reference to the bioclimatic classification by Rivas-Martínez (2004), these grasslands are linked mainly to thermo- to supramediterranean thermotypes (i.e., from sea-level up to ~900 m a.s.l.), with dry-subhumid ombrotypes.

Perennial bunchgrasses, such as *Brachypodium retusum*, *Hyparrhenia hirta*, *Macrochloa tenacissima*, *Ampelodesmos mauritanicus* and *Lygeum spartum* are the most frequent and typical representatives of this vegetation, classified by phytosociologists within the class *Lygeo sparti-Stipetea tenacissimae*.

Fig. 3 Characteristic Mediterranean grasslands and shrublands: (A) *Hyparrhenia hirta* grassland (*Hyparrhenion hirtae*, *Lygeo sparti-Stipetea tenacissima*), with *Asphodelus ramosus* in the foreground (E-Sicily), (B) *Lygeum spartum* grassland (*Moricandio-Lygeion sparti*, *Lygeo sparti-Stipetea tenacissima*) (S-Sicily), (C) annual dry grassland (*Trachynion distachyae*, *Stipo-Trachynietea distachyae*) with *Trachynia distachya* and *Lagurus ovatus* (SE-Apulia), (D) maquis of *Juniperion turbinatae* (*Pistacio lentisci-Rhamnetalia alaterni*), with *Juniperus phoenicea* and *Euphorbia dendroides* (SW-Sardinia), (E) early summer view of a coastal maquis with *Euphorbia dendroides* and *Periploca angustifolia* (*Periplocion angustifoliae*, *Pistacio-Rhamnetalia halepensis*) (W-Sicily), (F) submontane garrigue of *Armerio sardoae-Genistion salzmannii* (*Cisto-Lavanduletea stoechadis*), with *Cistus salviifolius*, *Erica scoparia*, *Genista desoleana*, *Tuberaria lignosa*, *Vincetoxicum hirundinaria* (NW-Sardinia). Photos by Riccardo Guarino.

In the meso-supramediterranean (and submediterranean) vegetation belts of the West Mediterranean Region, on siliceous cambic soils, *Stipa* and *Festuca* species form dense and bunchy grasslands, classified into the class *Stipo giganteae-Agrostietea castellanae*. These grasslands are dominated by *Celtica* (*Stipa*) *gigantea* on dry to subhumid lands and shift towards *Festuca merinoi* grasslands on northern and humid territories.

At mid-montane altitudes of the same region, geliturbate shallow soils are colonized by hemicrypto-chamaephytic communities, which can be classified in two main groups based on the type of substrate; acidophilous grasslands dominated by *Festuca indigesta*, *F. summilusitana*, *Koeleria crassipes* and *Plantago subulata*; basiphilous grasslands dominated by *Festuca hystris* and *Poa ligulata*. They are classified in the phytosociological orders *Jasiono sessiliflorae-Koeleretalia crassipedis* (*Festucetea indigestae*) and *Festuco hystricis-Poetalia ligulatae* (*Festuco hystricis-Ononidetea striatae*).

Semi-natural grasslands of *Poa bulbosa* ("majadales"), classified within the class *Poetea bulbosae*, are dense and short perennial grasslands resulting from the intense and continuous grazing of all the above mentioned grasslands. Besides the dwarf perennial grasses, the *Poetea bulbosae* include many legumes (mainly *Trifolium*, *Astragalus*, *Medicago*) and rosulate species (*Plantago*, *Echium*, etc.). These Mediterranean grasslands dry up in early summer but from the beginning of the autumnal rainy season they grow fast and remain green and fertile during winter. They are more frequent in the western Mediterranean, but also have been recognized in southern Italy and Greece.

The primary habitats of wintergreen perennial dry grasslands are rocky ledges and steep sunny slopes, where edaphic and microclimatic conditions favor the vigorous growth of the perennial bunchgrasses. Seasonal grazing, along with periodical early summer burning, has been traditionally adopted by the Mediterranean shepherds to create and maintain grasslands on the cheap. Secondary dry grasslands obtained in this way are one of the most common elements of the Mediterranean landscape. They are characterized by more or less dense tussocks of perennial grasses with interstitial space occupied by annual grasses. The density of perennial vs. annual grasses is greatly influenced by the soil compaction; excessive grazing pressure during the rainy season compacts the soil near the surface, which reduces infiltration, percolation, and water holding capacity, and concentrates roots near the surface (Menke, 1989). Differences in germination time and early seedling vigor may determine the competitive ability of one functional group against the other (Joffe, 1990; Garnier, 1992). Overgrazing, frequent burning and soil erosion can favor poisonous geophytes and hemicryptophytes belonging to the genera *Asphodeline*, *Asphodelus*, *Cachrys*, *Carlina*, *Drimia*, *Ferula*, *Iris*, *Mandragora*, *Narcissus*, *Ornithogalum*, *Thapsia*, etc. They occur throughout the southern, central and eastern Mediterranean Region and have their optimum under thermo-mesomediterranean bioclimate (Guarino and Pasta, 2017).

Wintergreen Ephemeral Dry Grasslands

Circum-Mediterranean thermo- to supramediterranean annual vegetation, which occurs sporadically also in temperate and Atlantic Europe, Macaronesia and the Saharo-Sindic region. It is dominated by small, poorly competitive annual grasses, colonizing nutrient-poor and seasonally dry soils. This vegetation is ascribed to the phytosociological classes *Helianthemetea guttati* (acidic grasslands) and *Stipo-Trachynietea distachyae* (calciphilous grasslands) (Rivas-Martínez, 1978; Brullo, 1985; de Foucault, 1999). Through ruderalisation, this vegetation may shift toward *Brometalia rubenti-tectorum* (*Chenopodietea*) communities.

Therophytic dry grasslands can develop on a variety of edaphic conditions, from loose sands to skeleton-rich shallow soils and heavily eroded slopes. The spatio-temporal changes in the composition and structure of the above-ground vegetation are closely related to those of the soil seed bank. Many annual plants show efficient germination at low temperatures, seed and fruit heteromorphism, as well as variation in seed dormancy among plant species and populations.

Disturbance plays a fundamental role in creating or maintaining the site conditions suitable for these ephemeral assemblages. Grazing, prolonged drought, and competition for limited soil resources may favor the annual strategy (Westoby, 1980). Frequent fires can be considered good allies of the perennial dry grasslands (see Bradshaw et al., 2011) but have an ambivalent effect on the establishment of annual dry grasslands, by reducing the chances of a viable seed bank establishment for many therophytes.

In spite of their limited resilience and functional stability, Mediterranean annual dry grasslands play a relevant ecological role by preventing the soil from rill erosion during the rainy season and by producing resources for a wide spectrum of seed eaters, pollinators and herbivores (Harper, 1977; Naveh, 1991; Guarino et al., 2005; Sánchez et al., 2017). Biological soil crusts dominated by annual plants, cyanobacteria, lichens and mosses are conspicuous in gypsum environments worldwide, and are important drivers of Mediterranean ecosystem processes such as carbon and nitrogen cycling, water infiltration and run-off and soil stability (Escudero et al., 2015).

Summergreen Perennial Dry Grasslands

In the Mediterranean Region, summergreen perennial grasslands can occur under a transition to temperate climate or wherever edaphic and topographic situations favor a later and longer-lasting vegetation period. Basiphilous summergreen grasslands are frequently found on mid-montane altitudes of the Iberian Massif (Serranía de Cuenca, Sierra de Gúdar) along the Apennines (up to Mt. Pollino; but see Gianguzzi et al., 2018) and the Balkans (up to northern Greece). These are species-rich grasslands, whose most conspicuous species in the Mediterranean are *Bromopsis erecta* and *Brachypodium rupestre*. Basiphilous grasslands dominated by *Brachypodium phoenicoides* may grow on meso-supramediterranean territories on deep clayey soils that retain soil moisture through the summer season. These grasslands are classified within the Eurosiberian class *Festuco-Brometea*, whose representatives, being well adapted to tolerate short periods of intense heat and drought stress, stretch into the North-Mediterranean Region. (In *Festuco-Brometea* vegetation on steep stony slopes of Southern Prealps, Lederbogen (1996) measured thermic peaks up to 50 °C and negative water balances up to –250 mm, due to the combined action of wind, solar radiation and limited water holding capacity of the soil.) On acidic and oligotrophic substrates, in the Iberian Peninsula, summergreen grasslands (“vallicares”) can grow on deep soils with occasional groundwater uplift, forming a dense and productive pasture that keeps green until midsummer. These meso-supramediterranean grasslands, characterized by *Agrostis castellana*, *Festuca ampla*, *Gaudinia fragilis*, are transitional to mesic grasslands of the class *Molinio-Arrhenatheretea*.

Typology of Mediterranean Shrublands

In the Mediterranean Region, four main structural and functional types of zonal shrublands can be recognized (Guarino et al., 2006), i.e., the semi-desertic halo-nitrophilous scrub in hyperarid coastal habitats and inland salt basins, the thermo-xerophilous dwarf shrublands, the thermo-xerophilous tall shrublands and the oromediterranean thorny cushion-like vegetation above the timberline (Fig. 3). The latter is not treated here.

Halo-Nitrophilous Shrublands

Under remarkably thermo-xeric climatic conditions, evaporitic sediments and marly to clayey substrata in the Mediterranean, Saharan-Atlantic and Macaronesian regions are colonized by open shrublands characterized by succulent *Chenopodiaceae* with a chamaephytic to nanophanerophytic habit, frequently growing together with representatives of the genera *Artemisia*, *Capparis*, *Peganum*, *Reaumuria* and *Limonium*.

These shrublands are ascribed to the phytosociological class *Pegano-Salsotea* (Brullo et al., 2012) and play an important ecological role against desertification in very dry and saline substrata, where the role of soil mesofauna in the decomposition of vegetation debris is limited. The soil organic carbon and total nitrogen pools of drylands are largely depending on symbiotic, nitrogen fixing bacteria associated with the rhizosphere and root endosphere of *Zygophyllaceae*, *Chenopodiaceae*, *Capparaceae*, *Tamaricaceae*, and others (Ahmad et al., 2006; Berendsen et al., 2012; El-Sayed et al., 2014), which can supply N for the plant growth. Individual shrubs can create areas of elevated soil nutrients and microbial activity, facilitated by the accumulation of wind-borne organic material under the shrubs and by the accumulation of ions next to the soil surface due to the evaporation. Nitrification runs fast under warm temperatures, neutral to alkaline pH and coarse soil texture. Therefore, it can be speculated that the immobilization of N during relatively wet and productive periods in winter and the mineralization of N during drier times, can contribute N for relatively rapid plant uptake as the system shifts to drought conditions.

Many species typical to the *Pegano-Salsotea* vegetation have succulent leaves, with big vacuoles where large quantities of ions can be accumulated, in order to facilitate the water uptake from a soil solution that has a low water potential. These morpho-anatomic and physiologic adaptations enable the plants dominating these communities to accumulate salts internally, or to excrete salts from cells and tissues (McKell, 1994). Although precise measurements are missing, it is likely that these plants need an intense solar radiation, because high levels of energy are required to keep the ionic pump efficient for the intracellular compartmentalization. Therefore, for these plants, an obligatory heliophily can be postulated.

Thermo-Xerophilous Dwarf Shrublands

The thermo-xerophilous Mediterranean dwarf-shrubs are locally named with different vernacular terms such as "tomillar," "matorral," "garrigue," "phrygana" or "bath'a." They are classified into the phytosociological classes *Ononido-Rosmarinetea*, related to base-rich substrates, and *Cisto-Lavanduletea stoechadis*, related to acidic siliceous and ultramafic substrates. This fire-resilient vegetation constitutes one of the most characteristic features of the Mediterranean landscapes. Matorrals or shrublands on base-rich soils bear a large number of species belonging to the *Lamiaceae* (*Nepeta*, *Salvia*, *Satureja*, *Sideritis*, *Teucrium*, *Thymus*), *Cistaceae* (*Helianthemum*, *Fumana*), and *Fabaceae* (*Anthyllis*, *Astragalus*, *Genista*, *Ononis*) families. On acidic siliceous soils, dominant plants mostly belong to the genera *Cistus*, *Lavandula*, *Genista*, *Halimium*, and *Ulex*. This vegetation displays several adaptations to tolerate both summer drought and heat stress, eventually ensuring a vigorous post-fire regeneration. Adaptations include deep rooting, persistent seeds, flammable secondary compounds, epidermal trichomes, sunken stomata, reduced leaf area, seasonal leaf dimorphism, and loss of leaves during the driest months (Orshan, 1972; Margaris, 1981; Christodoulakis, 1989; Christodoulakis et al., 1990; Kyparissis and Manetas, 1993; Gratani and Bombelli, 1999; Aronne and De Micco, 2001).

Many Mediterranean thermo-xerophilous dwarf-shrubs are used for the fragrance of their foliage. Aromatic oils have a threefold effect; they protect the plant against grazing, facilitate the ignition of wildfires, and reduce the loss of water vapor, as oils evaporate into the stomatal chambers (Margaris and Vokou, 1982; De Lillis, 1991). The root system, as well, helps these shrubs to cope with wildfires and summer drought: many species have deep roots and their young seedlings, typically germinating in autumn or winter, have fast-growing taproots that ensure an early root development away from the soil surface, thus limiting the effects of the summer drought. Moreover, most of the Mediterranean thermo-xerophilous dwarf-shrubs developed several symbioses with fungi and bacteria, so to increase the efficiency of nutrient-uptake (Kummerow, 1981; Puppi and Tartaglini, 1991).

Thermo-Xerophilous Tall Shrublands

The dense and tall woody assemblages belonging to this vegetation type are named with several different regional vernacular terms such as "madroñal," "maquis," "makia," or "ajmatan." (The thorny mantle communities (class *Crataego-Prunetea*) and the Balkan tall shrublands named "shibljak" deserve to be treated separately, because they host plenty of summergreen deciduous shrubs, small trees and lianas belonging to the temperate element) Most of these plant communities are placed in different orders of the class *Quercetea ilicis*, like *Quercetalia calliprini* in the East Mediterranean area, *Pistacio lentisci-Rhamnetalia alaterni* in western and central Mediterranean countries and *Pinetalia halepensis* in the arid sectors of South and East Mediterranean territories (Quézel and Médail, 2003).

Maquis communities are dominated by several small to medium-sized evergreen sclerophyllous and few lauriphyllous trees with sympodial growth (*Arbutus*, *Ceratonia*, *Juniperus Olea*, *Phillyrea*, *Pinus*, *Pistacia Quercus*, *Rhamnus Tetraclinis*, *Viburnum*, etc.), often tied together by lianas (*Asparagus*, *Clematis*, *Lonicera*, *Rosa*, *Rubia*, *Smilax*, etc.). The leaves of these species share many morpho-anatomical adaptations to Mediterranean climate. In fact, they are evergreen, sclerophyllous (coriaceous) and/or microphyllous, with the upper surface covered by hairs and/or waxes and the lower surface hairy and revolute. These traits help to mitigate the potential damages of solar radiation, to reduce water loss and to capture some overnight humidity. In areas prone to extremely severe and long-lasting

drought, species able to lose their leaves entirely during the summer months (like *Euphorbia dendroides*, *Periploca angustifolia*, *Rhus tripartita*, *Ziziphus lotus*) may prevail.

Thanks to effective resprouting and seed-dispersal strategies (Bond and Midgley, 2001; Higgins et al., 2008; Traveset et al., 2014), these woody species are able to recover after fire within few decades. The speed of woody encroachment and the “final” stage of local vegetation dynamics are strongly affected by the size, species richness and frequency of wooded nuclei and individual woody plants within the patchy and open landscapes (La Mantia et al., 2019). The intensity and frequency of disturbance shape the structure and the floristic composition of such communities, too. In many cases, frequent burning leads to species-poor and dense communities, dominated by a few resilient resprouters, like *Chamaerops humilis*, *Erica arborea*, *Phillyrea* spp. and *Quercus coccifera*, or the most stress-tolerant species, like *Euphorbia dendroides*, *Olea europaea*, *Pistacia lentiscus* and *Rhamnus oleoides*. Conifers—especially pines (*Pinus* spp.)—tend to dominate in areas subject to edapho-climatic drought stress (warm and arid areas, steep and S-facing slopes, well drained, base- and/or skeleton-rich thin soils) and moderately frequent fire disturbance, but may be completely wiped off if burning occurs too frequently.

The current distribution and the floristic patterns of Mediterranean maquis communities originate from millennia of anthropogenic disturbance and land use. Past human activities not only destroyed, altered and impoverished Mediterranean woodlands and shrublands (Henne et al., 2015), but also drove local vegetation dynamics towards results that are different from those expected according to local climatic conditions. For example, the thick soil layer accumulated over centuries on dry stone wall terraces may change the direction and enhance the speed of local vegetation dynamics (Rühl and Pasta, 2008).

The sides and beds of the seasonal and often large braided streams, mostly under thermo-mediterranean bioclimate, are characterized by species-poor thermo-hygrophilous shrublands ascribed to the class *Nerio-Tamaricetea*. These communities are dominated by few pioneer shrubs or small trees such as *Nerium oleander*, *Spartium junceum*, *Tamarix* spp., *Vitex agnus-castus*. These woody species are adapted to resist—or to rapidly respond by resprouting—the intense mechanical disturbance during the rainy season and to face extreme thermic conditions (up to 70 °C on the gravelly streambeds during summer) and long-lasting drought periods (up to 4–5 months). Most of them are poisonous and perform long-distance wind-dispersal.

On acidic soils, the hilly and submontane portions of the main mountain ranges of the West Mediterranean Region host dense tall shrublands dominated by several broom species (*Fabaceae* tribe *Genisteae*) of the genera *Adenocarpus*, *Cytisus* (incl. *Calicotome*), *Genista* (incl. *Teline*), *Retama* and *Ulex*. These communities are ascribed to the West Mediterranean-Atlantic class *Cytisetia scopario-striati* and form species-poor and dense communities on deforested areas as first seral stages, mostly linked to locally humid and cool mesoclimatic conditions. Most of the dominant species are poisonous and/or thorny, fast-growing, behave as seeders and/or resprouters after burning and play a major role in soil evolution thanks to N-fixing symbiotic rhizobia.

Origin of Mediterranean Grasslands and Shrublands

With the exception of the most archaic lineages (the so-called Tethysian and Palaeo-Mediterranean relict elements) and of the most recently immigrated species (i.e., those introduced by the human activities), all of the Mediterranean living organisms passed through massive and relatively recent adaptive radiations and speciation processes, which started in the late Miocene and are still ongoing. The biological history of the MG&S has been especially influenced by the Messinian salinity crisis (5.96–5.33 Ma), the formation of the Isthmus of Panama (around 2.8 Ma) and the Pleistocene climatic oscillations combined with glacial events (ongoing since 2.58 Ma).

Many of the thermo-xerophilous fire-resistant Mediterranean dwarf shrubs and tussock grasses derive from the so-called “Mediterranean flora.” They originated from a local adaptive radiation triggered by the gradual shifting from subhumid to semiarid climatic conditions, at the boundary between the tropical and the temperate zone, under evolutionary trends that probably begun during the Messinian disruption and exacerbated when the setup of the Isthmus of Panama changed the patterns of the oceanic currents and sharpened the seasonal climatic drought stress in the Mediterranean lands (Vargas et al., 2018).

The events associated to the Messinian age can be resumed as follows: due to the periodical obstruction of the Gibraltar Strait, part of the Mediterranean Sea dried up and reflooded several times. In the most critical periods, the sea was up to 1250 m shallower than today. Part of the continental slopes emerged, the bathyal floor turned into a patchy mosaic of sebkhas (salty drylands), salt-marshes and hypersalted, highly alkaline lakes (Hsu, 1973). Erosion increased everywhere, diverse rocks became rapidly exposed. The indirect uplift of mountain ranges gave rise to huge rockfalls and massive debris flows. The topographic diversity increased and, as mountain ranges were rapidly rising up, hundreds of new canyons and gorges were incised into them, steep slopes came into existence and divergent localized microhabitats developed everywhere. Plenty of new ecological niches were ready to be colonized by pioneer plants with different adaptations (Bertolani-Marchetti and Cita, 1975; Bocquet et al., 1978; Thompson, 2005). For instance, the *Pegano-Salsolitea* vegetation derives from Irano-Turanian and Saharo-Arabian chorotypes, whose pristine elements spread into the Mediterranean Basin during the Messinian salinity crisis (Suc et al., 2018).

As a consequence of the Messinian age and of the subsequent climatic changes, which increased the seasonal aridity on the Mediterranean lands, the ancestors of the MG&S passed through a new adaptive radiation. The driving forces of the speciation wave, which is still characterizing the Mediterranean flora, are the following (Raven, 1973):

- *Geographical segregation and appearance of new lands*: as the level of Mediterranean Sea fluctuated several times during last 6 Ma, many currently isolated lands have been repeatedly connected to the mainland. Some plant species growing in the MG&S are

- neoenemics, deriving from the splitting of a formerly continuous distribution range; some examples are provided by the phylogenetic groups named *sensu lato* after *Anthyllis vulneraria*, *Bromopsis erecta*, *Brachypodium pinnatum*, *Centaurea deusta*, *Heli-anthemum nummularium*, *Stipa pennata*, *Thymus serpyllum*.
- *Climatic variations*: the Mediterranean climate is not only depending on the latitude, but also on the cyclonic circulation of the oceanic air masses (Azores High), whose influence and effects are ranging year by year. Annual climatic variations and major climatic changes may locally lead to the severe reduction and splitting of metapopulations. Several noticeable disjunctions in the distribution ranges of plant species growing in the Mediterranean dry grasslands can be attributed to these climate changes. For example, the disjunct Sicilian populations of *Heteropogon contortus*, *Artemisia alba*, *Sesleria nitida* subsp. *sicula*, *Koeleria splendens* and *Helictotrichon convolutum*, have probably reached the island in the Pleistocene, during the dry interglacial periods. Moreover, long periods of high climatic variability can favor an evolutionary trend towards the adoption of annual life strategies.
 - *Substrate heterogeneity*: in the Mediterranean lands, several outcropping rock types are represented. Due to the few or no frost days and the relatively scarce rainfall, soils reflect quite precisely the chemical composition of the parental rock material. Different soil chemistry and texture select different floras; noticeable examples are provided by the phytosociological classes *Ononido-Rosmarinetea* and *Stipo-Trachynieta distachyae*, related to base-rich substrates, versus *Cisto-Lavanduletea stoechadis* and *Heli-anthemetea guttati*, related to calcium-poor acidic siliceous and/or ultramafic substrates.
 - *Rich fauna of pollinators*: the fauna of pollinators is far richer in the Mediterranean Region than in the neighboring temperate and semiarid ones. We know that many insects are quite precise in their flower-visiting habits, and in the Mediterranean dry grasslands and shrublands several examples of coevolution between flowers and insects are known, especially among representatives of the families *Fabaceae*, *Lamiaceae*, *Plantaginaceae* and *Orchidaceae* (Galloni et al., 2007; Bradshaw et al., 2010; Vargas et al., 2017).
 - *Short generation time*: the intense gene flows characterizing short-lived organisms may easily promote random gene fixation and subsequent divergent genotypes, which can efficiently occupy new niches in the patchy mosaic of the Mediterranean landscapes, particularly in ecologically marginal or geographically peripheral populations. Noticeable examples of micro-evolutionary processes promoting population differentiation at local scale are provided, for instance, by the species complexes of *Senecio* sect. *Senecio* (Comes and Abbott, 2001), *Silene* sect. *Coloratae* (Valsecchi, 1995; Brullo et al., 2015), *Rumex bucephalophorus* (Press, 1988) and *Dianthus* sect. *Sylvestris* (Bacchetta et al., 2010).

These evolutionary trends in Mediterranean dry grasslands overall lead from long-lived, big-seeded, monochorous plant species toward short-lived, small-seeded, polychorous species (Pignatti, 1978, 1979). Some examples of primitive plant species, still showing ancestral features, are found in the *Lygeo-Stipetea* vegetation of some isolated Mediterranean districts; this is the case, for instance, of *Astragalus huetii*, endemic to a small area of inner Sicily, *Astragalus verrucosus*, endemic to a small area of SW Sardinia, and *Asperula crassula* restricted to Crete. Many species typical of the *Lygeo-Stipetea* derive from the paleotropical Paleogene flora and are often characterized by very disjunct, sometimes amphi-Saharan distribution ranges. For example, it is likely that the *Lygeum spartum* grasslands of Southern Crete and northern Egypt, representing the easternmost disjunct outposts of the *Lygeum spartum* distribution range, remained isolated in those districts since the end of the Messinian age (Marcenò et al., 2019).

The already mentioned, evolutionary trend toward short-lived life strategy often coincide with the tendency towards rewardless, species-specific pollination strategies and high investment in seed productivity (Dafni, 1987). Obligate seeders have greater numbers of sexually produced generations, resulting in greater genetic recombination, which in turn contributes to more rapid speciation processes. This could explain why the Mediterranean Region has such a high diversity of plant and insect species if compared with the temperate European ecosystems (Médail and Quézel, 1997).

Examples of how the ancestors of Mediterranean therophytes could have looked like, are quite rare in the perennial dry grasslands; yet grasslands are ruled by competition and intense dynamism. Instead, woody ancestors of present-day herbaceous species occur on Mediterranean cliffs; *Linum arboreum* looks probably rather similar to the ancestors of the Mediterranean yellow-flowered annual flaxes; the same holds true for *Bupleurum dianthifolium* versus *B. baldense*, *B. fontanesii* and allied taxa; *Tuberaria lignosa* vs. *T. guttata*, and other similar examples reported by Pignatti (1979). As a matter of fact, secondary woodiness may also represent a recently acquired trait which has been triggered repeatedly in insular and insular-like realms, thus enabling annual and biennial herbs to better fit with recently colonized habitats (Nürk et al., 2019).

The Mediterranean *Festuco-Brometea* vegetation is derived from Holarctic and Eurasian elements that probably reached and colonized the Mediterranean Region during the Pleistocene glacial events, together with herds of wild herbivores. During the glacial maxima, the North-Mediterranean territories experienced a non-Mediterranean or feebly Mediterranean climate, and they acted as refugia for several species coming from the north (Feliner, 2011). Migratory patterns of plants and animals along latitudinal gradients became established, and new ecological niches became available for a new adaptive radiation. Therefore, the Mediterranean patches of *Festuco-Brometea* vegetation are the last shreds of a vegetation type that was probably much more widely distributed during the dry interglacial periods. In the Mediterranean Region, this vegetation is nowadays restricted to the main mountain ranges of the southern European countries, especially where the fully Mediterranean climatic conditions are buffered by the condensation of orographic moisture, as it happens along the Apennines. In some cases, the postglacial isolation of *Festuco-Brometea* species on the Mediterranean uplands originated new endemic taxa, such as *Phleum ambiguum*, *Sesleria nitida*, *Astragalus sirinicus*, and *Crepis lacera*.

Similarly, in the case of Mediterranean shrublands, some elements are related to the humid palaeotropical Paleogene flora coming from the African plate, whereas others are related to the cool temperate so-called “Arcto-Tertiary flora” (Raven, 1973; Axelrod, 1975; Quézel, 1995; Rundel et al., 2016).

Representatives of the first group are the “desert disjunct” genera, which evolved in the African plate during the Cretaceous and moved northwards through the Saharan Region during the early Paleogene, when the Sahara was not as desertic as today. This is the case of genera like *Ceratonia*, *Chamaerops*, *Cotinus*, *Erica*, *Laurus*, *Myrtus*, *Olea*, *Paliurus*, *Phillyrea* and *Phoenix*, which now have in the Mediterranean shrublands the north-western limit of their distribution range (Palamarev, 1989).

Representatives of the second group are the so called “Laurasian” genera, whose representatives are also found in Eurasia and North America. This is the case of species belonging to genera like *Acer*, *Arbutus*, *Cercis*, *Clematis*, *Crataegus*, *Cupressus*, *Fontanesia*, *Fraxinus*, *Juniperus*, *Liquidambar*, *Lonicera*, *Pinus*, *Platanus*, *Prunus*, *Quercus*, *Rhamnus*, *Rosa*, *Rubus*, *Salvia*, *Smilax*, *Styrax*, *Viburnum*, *Vitis*, *Zelkova*, etc., which often meet in the Mediterranean shrublands the southern limit of their distribution range.

Some evolutionary trends associated to the species growing in the Mediterranean shrublands are quite coherent to those observed in the Mediterranean dry grasslands; from evergreen to drought-deciduous, from long to short life cycle, from dioecy to hermaphroditism, from fleshy few-seeded fruits to dry many-seeded ones (Herrera, 1992; Aronne and Wilcock, 1994). All these trends can be seen as the result of a local evolution, triggered by the progressive increase of both summer drought and fire occurrence, under the selective pressure of limited soil nutrient and water availability.

Until recent times, the scientific community is still lively debating whether the opening and the fragmentation of natural landscape across Mediterranean Region was mostly climate-driven (e.g., Di Rita et al., 2018) or more due to anthropogenic pressure (e.g., Tinner et al., 2016). The truth is probably in the middle; although many recent researches point out that human impact was able to cause deep and sudden changes in tree cover, and even the local destruction of entire forest ecosystems, the extension of Mediterranean forest habitats prior to human disturbance has probably been overestimated; grasslands and shrublands being more common than expected even before the onset of the first human communities (Feurdean et al., 2018).

Ecology and Biodiversity Patterns

The Mediterranean Region stretches over approximately 3800 km west-east and 1000 km north-south (Fig. 1). This creates a very strong biogeographic contrast between the western and the eastern halves of the Mediterranean. A marked biogeographic boundary runs north-south through the Sicily-Tunisian “sill”. Indeed, it has been recognized a western “Atlantic-Mediterranean” subregion, and an eastern “Ponto-Mediterranean” subregion, strongly influenced by immigration of Irano-Turanian elements. Historical and current-day differences in climate, in particular rainfall and seasonal aridity, are more extreme from east to west than they are in a north-south direction (Thompson, 2005). The water deficit ranges from an average of 2 months in the west Mediterranean to 5 months in the southeast Mediterranean Region (Blondel et al., 2010). Though this is an overall pattern, even within the Iberian Peninsula aridity is very contrasted from the proximity to the Atlantic Ocean toward the Southeast, with some scattered areas under a Mediterranean desertic bioclimate (0.17% of total area of Iberian Peninsula and Balearic Islands; Rivas-Martínez et al., 2017). Biogeographically, in addition to the Western and Eastern Mediterranean, a North African Mediterranean subregion, can be recognized (de Foucault, 1993; Valdés et al., 2002; Rivas-Martínez, 2007; Taleb and Fennane, 2018). However, the floristic and ecological differences between northern and southern Mediterranean lands become less evident in the west, due to the similarity of the southern Iberian Peninsula to the Moroccan Rif, resulting from a common geological history (Valdés, 1991).

Though the summer drought stress is the essence of the Mediterranean climate, another important climatic constraint is the winter cold stress, whose length and intensity depends on the altitude and exposure (Guarino, 2001). These climatic factors limit the plant species distribution and also determine the floristic composition of MG&S along the gradient from the infra-mediterranean to the cryo-oromediterranean vegetation belts.

Also, continentality influences the vegetation distribution at local scales. Remarkable differences in the daily and seasonal temperature ranges occur in the largest Mediterranean mainland, such as the Iberian and Balkan Peninsulas, in which the peripheric disposition of the mountains limits the oceanic influence of the sea on the interior territories. For instance, the difference between the warmest and coldest month can reach 22 °C in central Spain (La Mancha).

The strong seasonality is a main environmental driver conditioning the insect populations of dry grasslands. The number of individuals is subject to seasonal fluctuations (Stamou, 1998). The temporal distribution of the main food resources (sprouts, leaves, flowers, seeds) allows most insects of these habitats to develop only one generation per year. For example, in synchronism with the abundant production of pollen by many herbaceous plants, there is a clear spring peak of abundance of flower-visiting beetles. The peaks of abundance of the herbivory correspond to those of the predators such as the spiders; in particular the wandering spiders, which do not build webs (e.g., *Salticidae*).

Substrate plays a primary role in the composition of regional grasslands and shrublands, more important than in Mediterranean forests. Most of the Mediterranean mainland is covered by calcareous sedimentary rocks. Magmatic and metamorphic siliceous (acidic) rocks dominate in Iberian-Atlantic region, Corsica and Sardinia, while these are less common in the rest of the Mediterranean Region. Overall, a wide range of substrates, from crystalline (granite, gneiss, quartzite, schists, sandstones, etc.), to calcareous (limestones, dolomites) and sedimentary rocks (marls, gypsum, etc.), turns into a high community diversity. The floristic affinity of silicicolous Mediterranean Iberian-Atlantic and calcicolous eastern-Iberian grasslands and shrublands is weaker than that between the western and eastern Mediterranean calcicolous ones. Many more vegetation units occur on base-rich substrates than on acidic substrates (Mucina et al., 2016), probably because of the larger extension and varied lithology of Mediterranean limestones, but nutrient-poor acidic soils support a high level of regional endemism throughout the Mediterranean Region (Rivas-Martínez, 2011).

The ancient Mediterranean civilization is largely known as a main determinant in shaping the Mediterranean vegetation landscape and biodiversity. However, before arrival of humans, the Mediterranean landscape was already a natural mosaic. It is known that fires have occurred naturally at least since the Miocene. From the onset of Neolithic, burning was a constant practice as humans learnt how to use fire to create pastures and prepare soils for cultivation. The use of fire began earlier in the Mediterranean than elsewhere in Europe (Thompson, 2005). Also, there was an abundance of native populations of wild herbivores, including deers (*Cervus elaphus*, *Dama*, *Capreolus capreolus*), large bovids, such as the aurochs (*Bos primigenius*), the European bison (*Bison bonasus*), and also of the Eurasian wild horse (*Equus ferus*) (Casinello, 2012). This resulted in a high grazing pressure and a long history of a continuous adaptation of plants to grazers.

Extensive livestock rearing has been an essential economic activity for millennia in the Mediterranean Region, especially on acidic nutrient-poor soils, rocky and rugged areas, whereas fertile soils were predominantly used as arable fields. One specific Mediterranean landscape is the “dehesa” or “montado,” very extended in Sardinia and in the western and southwestern quadrants of the Iberian Peninsula, consisting of open oak woodlands occupying gently sloping or flat areas. In the understorey, there can be crops, pastures and shrublands. Pastures comprise a mosaic of acidophilous annual ephemeral grasslands, subnitrophilous Mediterranean grasslands, *Poa bulbosa* grasslands and “vallicares.” Shrublands comprise tall broom-like communities (*Cytisetea scopario-striati*) and garrigues (*Cisto-Lavanduletea*). Dehesa and montado are associated to an agro-sylvo-pastoral system resulting from the co-evolution of man and nature in a difficult environment (San Miguel, 1994) and promotes a high biological diversity (Eichhorn et al., 2006; Díaz and Pulido, 2009).

Ecosystem services

Mediterranean grasslands and shrublands are of paramount importance for delivering a wide array of ecosystem services. (According to the Millennium Ecosystem Assessment (2005), there are four main classes of ecosystem services: Provisioning services are those related to the products people obtain from ecosystems, such as food, fuel, fiber, fresh water, and genetic resources. Regulating services are the benefits people obtain from the regulation of ecosystem processes, such as air quality maintenance, erosion control or water purification. Cultural services are the non-material benefits people obtain from ecosystems through spiritual enrichment, cognitive development, recreation, and aesthetic experiences. Supporting services are those that are necessary for the production of all other ecosystem services, such as primary production and soil formation.) They sustain not only economies and societies but also many elements of the local biodiversity. Apart from their importance for the maintenance of biodiversity, they play a major role in providing high quality forage for both livestock and wild animals; they support communities of insects with major roles in the ecosystem services of control and pollination; they sustain apiculture, and contribute to the prevention of erosion processes and maintenance of the water cycle; they buffer the negative impacts from fertilizers and pesticides and display highly significant aesthetic and recreational values (Vrahnakis et al., 2013).

Provisioning services obtained by MG&S are the most prominent, with grazing-related goods being at the top of these values. From the onset of livestock husbandry, MG&S were offering their natural resources for feeding animals and humans as well. It is believed that during the Paleolithic age there was a positive interplay between humans and Mediterranean grasslands; the shift of human population generated greater disturbances on grasslands, which in turn controlled competitive advantages and increased the human ecological fitness (Pignatti, 1978). The intensity of this interplay was getting higher when an extensive selection and domestication of the most productive breeds was taking place during the Neolithic age. It seems that there was a triple co-evolution of grazing systems, human systems and the capacity of MG&S to provide their goods and services. For example, the traditional grazing system of nomadism, which is still practiced in some places of the Mediterranean (e.g., in Sierra de Gredos (center of Spain); in northern Pindus mountain (Greece); in Molise, Apulia and Abruzzo (southern Italy)), played an important role for the development of human cultures in sites unsuitable for sedentary settlement (Ispikoudis et al., 2004).

The provisioning service of grazing still plays an important role in the Mediterranean societies. In terms of animal units, the south-European Mediterranean lands (Spain, Italy, France, Greece, Malta and Portugal) hold more than 15 million cattle, 9 million goats, 30 million sheep and 0.5 million horses, while north-African Mediterranean lands (Algeria, Egypt, Libya, Morocco and Tunisia) hold 10 million cattle, 15 million goats, 60 million sheep, and 0.2 million horses (roughly estimated by data provided by FAO, 2014). These animals use extensively the feeding resources provided by almost 100 million ha of land occupied by MG&S. Grazing produce a series of meat and dairy products benefits, quite often of high nutritive qualities, certified by European Community as products of “Protected Denomination of Origin” (PDO), “Protected Geographic Indication” (PGI) and “Traditional Specialties Guaranteed” (TSG). Such products are linked to cultural heritage for consumers and sustain social cohesion, by connecting rural and urban populations (Zander et al., 2014). Also, high natural value farming (HNVF) that takes place in dehesas and montados produces a variety of (a) economic benefits, such as increase in farm income through multiple uses of natural resources, increase security against market perturbations; (b) social benefits, such as employment stability in the expense of depopulation; (c) environmental benefits, such as mitigation of desertification, contribution to the resilience of the ecosystem against climate change, decreasing fire risk, ecological corridors and refuges for large mammals and birds of prey (Sequeira, 2008). For example, the threatened Spanish Imperial Eagle (*Aquila adalberti*) and Black Vulture (*Aegypius monachus*), nest in montados and dehesas and meet their feeding demands in the open grasslands (Bugalho and Abreu, 2008; Vrahnakis et al., 2009).

MG&S play also a crucial role in preventing land degradation. They operate against soil loss due to water and wind erosion, with soil retention capacity generally lower than arable land (Cerdan et al., 2010). The tussock grasses typical to the wintergreen thermo-

xerophilous grasslands provide suitable microclimatic conditions (shade, water through overnight dew accumulation, etc.) for many annual plants and play an essential role for soil organic carbon storage (Novara et al., 2013). In addition, Mediterranean grasslands serve as fire breaks, so reducing fire risk (Úbeda et al., 2005).

Although MG&S largely contribute to the overall Mediterranean carbon balance, there are few available studies concerning the biomass and the net ecosystem exchange capacity of MG&S communities. Additionally, the above- and below-ground biomass of such communities shows a wide variation, which depends on the intensity of local stress factors and on the nature, intensity and frequency of disturbance (Pasta et al., 2015).

Apart from the above-mentioned ecosystem services, the cultural value of MG&S is of great importance for the Mediterranean people, traditions and history. Quite often rural civilizations are based on the use of natural resources provided by MG&S. For instance, the traditions of “Sarakatsani,” traditionally transhumant shepherds in continental Greece, were deeply influenced by the phenology of MG&S, determining livestock keeping activities. Traditional Sarakatsani settlements were located on or near dry grasslands and their life centered year-round on the needs of their flocks (Clogg, 2002). Nowadays, the revival of old traditions of Sarakatsani take place during their annual meetings (αντάμωμα = antamoma), in specific areas of open semi-natural dry grasslands, thus reflecting their strong cultural bonds with this vegetation type.

Threats

According to the homeorhetic hypothesis, there is a dynamic equilibrium of human and natural perturbations and climatic fluctuations in Mediterranean (Waddington, 1975; Guarino, 2006). This triplet of perturbations may form the possible sources of threat for MG&S, i.e., human, climate and natural (biotic, abiotic) environment. For MG&S, the dynamic equilibrium happens at the expense of soil stability and productivity, in cases when human—via uncontrolled pastoral activities—uptake nutrients rapidly, while the return rates are very low. Coupled with increased erosion risks, the new equilibriums are characterized by low energetic rates, and soil degradation lead to desertification, which poses severe threats for MG&S (Waddington, 1975; Guarino, 2006; Ambarlı et al., 2018).

Climate change is an important threat for MG&S. In particular, the Mediterranean is expected to experience more intense dry-heat conditions by further increasing atmospheric temperature and reducing precipitation (Hulme, 1999), thereby reducing soil moisture (Déqué et al., 1998). The available soil moisture affects the growth and survival of plants, affects the carbon and nitrogen cycle and, consequently, affects the floristic composition of ecosystems (Cheddadi et al., 2001). Ecosystems in areas with dry heat conditions are the most vulnerable to these climate changes (Schröter et al., 2005). Of course, it is difficult to distinguish in practice the effects of climate change from those of long-term disturbances of these ecosystems, such as overgrazing, fires, logging, and air pollution (Naveh, 1995; Pausas, 1999). Degradation, area and species loss, currently observed in many MG&S, is largely a result of overgrazing (Asner et al., 2004). Climate change, coupled with intense grazing, can threaten the biodiversity, productivity and stability of MG&S, and increase the risk of desertification (Scheffer et al., 2001).

It is well established that in order to withstand soil degradation and combat desertification, grazing capacity must be in balance with livestock density (Holeček et al., 2004). The overgrazed MG&S dominated the Mediterranean open landscape in the past, and still dominate where communal grazing is taking place (Roukos et al., 2013; Kairis et al., 2015). However, this is not the case in the present. It is rather the undergrazed aspect of vegetation that characterizes the MG&S nowadays (Ambarlı et al., 2018). This is mainly attributed to the decline of the mountain rural communities and to the abandonment of traditional practices, resulting in shrub encroachment, biodiversity loss and consequent accumulation of organic flammable material (Peco et al., 2006; Zomeni et al., 2008; Metera et al., 2010).

MG&S co-evolved with humans. In the past, the level of human intervention in the spatio-temporal distribution of MG&S was adjusting to the increased needs. However, the uptake of productivity was taking place in a way that a balance was kept in favor of nature's resilience. For example, given the restricted availability of palatable green biomass in the xerothermic periods, when animal feeding demands were increasing, rangelands were burnt every 5–10 years in the past, so to control the density and spreading of unpalatable chamaephytes of *Ononido-Rosmarinetea*, and *Cisto-Lavanduletea stoechadis*. While fire-controlled areas experienced the short-term catastrophic effect of fire, the medium-term effect is considered beneficial for nature (floristic diversity) and man (increased quality of regenerated forage material), as well (Vrahnakis et al., 2004). In addition, shrub and tree encroachment is prevented, as fire and subsequent grazing by goats control the expansion of woody species (Noy-Meir, 1995).

Shrub and tree encroachment are indirectly supported by the economic framework that often is set by state agricultural strategies. One of the major driving forces for recent alterations may be found in European Commission's system of subsidies that favor agricultural intensification and expansion of arable lands (Chouvardas and Vrahnakis, 2009). For example, in recent year, large areas of the formerly used summer pastures have been abandoned and the subsidies provided to halt this trend are used by the local communities to make the mountain pastures more accessible. Therefore, shepherds are indirectly encouraged to move from the pastures to the villages carrying hay and concentrates to feed their stocks during the critical periods. Such practice facilitates the turn of an extensive production process into a more productive, but more restricted and intensive exploitation of the land. As a result, large parts of the Mediterranean former rangelands are nowadays shifting toward shrublands and woodlands, if abandoned, or toward *Onopordetea acanthii* vegetation through overgrazing (Bauer and Bergmeier, 2011; Bianchetto et al., 2015).

The recent demographic changes that occurred in Mediterranean Region have often detrimental effects on natural vegetation of high value. Urban sprawl processes taking place in European cities constitute an important problem opposing sustainable growth

and environmental protection. This is particularly evident in the Mediterranean, where intense tourism development and “coastalization” continuously impose urban land pressures on agricultural areas and natural land (Cori, 1999; Ivanov et al., 2009). For example, coastalization has severe impact on the vegetation of *Pegano-Salsoletea*, which is represented by several interesting and well differentiated phytosociological units. Also, most of the sites colonized by this vegetation have an outstanding stratigraphic and geo-morphological interest for Quaternary/Pleistocene lower boundary and the early stage of Pleistocene (Gibbard et al., 2010). The proximity of high value MG&S to areas of rapid population growth and urban development is a source of increasing concern, also because the naturalistic and scientific value of such vegetation is ignored by most, and the public access to sensitive habitats/biotopes is totally uncontrolled. For example, it is estimated that in the last three decades, 80% of the *Limonio opulenti-Salsolietum oppositifoliae* habitat was lost, even if some floristic reminiscences of the former vegetation can still be found in the town of Porto Empedocle (southern Sicily). The same holds true for the many “badlands” that, due to the waterproof properties of the clay, have been transformed into landfills for the urban solid waste. This is the case, for instance, of the habitat formerly occupied by the *Capparido siculae-Salsolietum oppositifoliae*, near the town of Adrano, Italy (Brullo et al., 2012).

Impacts from human activities are resulting in a severe habitat loss and declining environmental quality. Roads, dust, pollution, industrial activities, uncontrolled off-road access, are limiting factors in the population dynamics of the most sensitive species of MG&S. Moreover, the overall disturbance can increase the competitiveness of nonnative species, opening the way to multiple problems, such as the potential to out-compete native species, habitat alteration and alteration of the trophic levels.

Conservation, Sustainable Management and Restoration

The close relation of the historical evolution of MG&S vegetation and human societies supports their consideration as socio-ecosystems (Hutsinger and Oviedo, 2014). Within these mutually-dependent socio-ecosystems, characterized by a variety of management, ecosystem services provided by MG&S appear along a gradient of intensity of their resource use.

The majority of MG&S are maintained by a combination of natural and human caused disturbances, such as extensive historical clearings, seeding, flooding, fertilization, burning, grazing (Papanastasis, 1999; La Mantia et al., 2007) and would succeed to natural shrublands in the absence of such disturbances. If an extensive grassland management is abandoned, the natural succession will favor shrubs. According to Fuhlendorf (1997), shrubs exhibit specific characteristics that support significant competitive advantages over herbaceous species, like exponential growth rate, higher tolerance to nutrient or water stress, chemical or physical deterrents to browsing, vegetative reproduction, extended longevity. It is well-documented that as shrub assemblages of the Mediterranean Region become thicker, total biodiversity declines (Vrahnakis et al., 2005). Thus, grazing seems to be a valuable tool in controlling shrub and tree invasion and must be incorporated into management plans.

The European Red List of Habitats assessed that 60% of dry grassland habitats are threatened to some degree, and it includes some Mediterranean types, while only one Mediterranean shrubland habitat is threatened (Thermomediterranean scrub) (Table 2). With few exceptions, the large majority of the aforementioned MG&S are protected by the 92/43 “Habitats” EU Directive. Additionally, many species living in these habitats are listed in the Annexes of international and European conventions and/or figure within national and regional red-lists compiled according to IUCN criteria.

On the other side, those legal measures are often neglected and unattended. As a consequence, wide areas covered by grasslands and nonforest woody communities, especially on the plains, near the cities and along the coasts, currently suffer from urban sprawl and land use intensification (e.g., expansion of greenhouse agriculture wiped out large surfaces covered with grasslands and shrub communities along the coasts of S Spain, SE Sicily, SE Crete, etc.). The conservation of such plant communities should go beyond the administrative limits of the Mediterranean countries. Scientists, politicians and other stakeholders should try to interact in order to set up internationally shared measures aiming at maintaining the best preserved patches of grassland and shrubland.

In order to verify the short- to medium-term effect of land use changes, an international scientific network should be built up in order to perform regular and accurate monitoring of the impact of the main disturbance factors (e.g., overgrazing/undergrazing, fire regime, plant invasion) on the aforementioned ecosystems. In our opinion, the most effective way to conserve Mediterranean ecosystems is the adoption of dynamic and flexible management strategies. On this purpose, we should learn from (and teach once again) the past extensive land use practices. In fact, moderate (low-intensity- and low-frequency-) disturbance induced by extensive land use allows the self-maintenance of mosaic-like landscapes where frequent patches of tall and dwarf shrublands may co-exist with grasslands. Hence, extensive land use practices should be legally and financially supported by Mediterranean countries in order to obtain dynamic, yet steady habitats and landscapes. To do this, ad hoc legal and political strategies should be developed in order to maintain sustainable farming and agro-forestry activities, like transhumance, dehesas and montados, which allow extensive grazing fitting with the carrying capacities of local pastures, tree exploitation and grassland improvement through the sowing of forage species; extensive cultivation of drought-tolerant crops and fruit trees, providing plenty of suitable habitats for many thermo-xerophilous annual and biennial herbs and grasses; rational (cyclic) coppicing of tall shrublands to provide precious ecotones. By creation of clearings, the local biodiversity can be enhanced. For example, flower visiting insects, are observed above all where ecotonal vegetation develops, with a high diversity of flowering plants, especially herbaceous ones. This means that the structure of these insect communities, in the forest/shrubland/garrigue mosaic of evergreen vegetation, is based on a dynamic balance that is continually renewed through natural mechanisms such as fire and grazing. Moreover, as urbanization is increasingly affecting the plains and the coasts of all Mediterranean countries, more efforts should be addressed in order to find out the best technical “nature-based” solutions to create networks of functionally interdependent plant communities (e.g., *Lygeo-*

Table 2 Mediterranean grassland and shrubland types and their relationships to habitats of the European Red List (RL; Janssen et al., 2016), phytosociological units (Mucina et al., 2016) and Annex I of the “Habitats” 92/43 EU Directive.

^aIt also includes upper supramediterranean levels, below the timberline.

Stipetea and *Helianthemetea guttati*) by exploiting the suburban brownfields and the roofs of the buildings of expanding cities (Catalano et al., 2013).

Sustainability of ecosystem services should be the main target of MG&S management (Varela and Robles, 2016). To achieve sustainability, a balanced interplay between all aspects of ecosystem services, and especially the control of the impact of human and climate constraints that may alter regulating and supporting services, must be well incorporated in management plans (Cavender-Bares et al., 2015). In addition to sustaining socio-economic systems that are based on MS&G, the natural capital is needed to maintain them. In that sense, issues related to property rights, land tenure, policies aimed at promoting the sustainable use of MS&G and resilience of socio-ecosystems must be adequately incorporated and discussed in the framework of management plans. Integrated management plans (IMPs) are urgently needed. They should include on the one hand a zoning framework to protect key habitats and species from detrimental human activities, as well as to allow (and suggest) appropriate sustainable uses, and on the other hand adequately address the socioeconomic relations expected to develop with the other aspects of local and regional or even state economies. Moreover, the abandonment of traditional management practices may deprive sustainable ways of human intervention in MG&S. Thus, such traditional practices must be detected and included (thus preserved) in the IMPs. It is to be hoped that, in the future, people and resources will be found in order to make more resolvable the conflict between human activities and conservation needs.

The management of MG&S may be based on four principles; (a) ecosystem sustainability, (b) natural regeneration, (c) multiple purposes, and (d) protection (Papanastasis, 2009). Advances in research into the ecological characteristics, structure and functioning of MG&S ecosystems, new socio-economic conditions and new trends and proven practices are upgrading or enhancing this four-principle management framework. Ecosystem sustainability has its roots in American forestry practice (Chapin et al., 1996). An ecosystem is considered sustainable when, during the natural cycle of disturbances, it maintains (a) the characteristic diversity of its major functional groups, (b) soil fertility and productivity, and (c) effective biogeochemical nutrient cycles. According to this concept, it is necessary to safeguard and protect the structural and functional characteristics of MG&S, in order to ensure the sustainable outcome of their operation, i.e., their productivity. The principle of natural regeneration requires measures to enhance the natural continuity of vegetation in space, but mainly over time. This principle is of particular importance nowadays, as the continuous underuse of MG&S (e.g., undergrazing, cease of firewood collection) over the last decades has resulted in the natural expansion and thickening of woody vegetation at the expense of grasslands (Zomeni et al., 2008). The multipurpose principle calls for the multifunctional role of MG&S to be highlighted. In line with this principle, as well as the ecosystem perception, the adoption of specific principles and criteria for the certification of products and services based on the MG&S is expected to highlight their important multifunctional role. The principles for Forest Stewardship (FSC, 2002) can be used as a template for this certification. Finally, the principle of protection requires the adoption of all those institutional measures, in particular, which will help to reduce the impact of the causes of degradation on the MG&S.

Abstract

Scrub communities dominated by heathers are called heathlands and are frequent in western and central Europe and in the subalpine belts of the mountains. They are diversified into seven subtypes along a wide geographic span along the entire Atlantic countries of Europe, from the Cape North to the Strait of Gibraltar as well as the Azorean islands, and penetrate in some areas of central Europe. They always grow on siliceous soils poor in bases and require high moisture during the growing season. The organic matter produced by heathlands is acidic and favors the podsolization of the soils. Most of them are linked to the human activity based on traditional land use: extensive grazing, harvesting and fire, which supported an agrarian economy based in livestock: sheep, goats, cattle. They started expanding from the Neolithic on at the expense of the forests that existed before. With the current rural abandonment, heathlands are severely diminishing and being replaced by newly growing forests or other human induced vegetation types such as grasslands, tree plantations or fields.

Delimitation and Physiogeography [Topography, Climate, Soils] of the Region

Heathlands have been considered one of the most genuine European landscape types (Gorissen, 2004), being particularly widespread in its Atlantic zone (Gimingham, 1972). The word heathland is used to name a treeless area covered by heath, a term used to name an evergreen scrub vegetation formed mostly by heathers, i.e. dwarf-shrubby species of the *Ericaceae* family, basically of the genera *Arctostaphylos*, *Erica*, *Calluna*, *Daboecia*, *Empetrum*, *Loiseleuria*, *Rhododendron* and *Vaccinium*. A number of woody legumes may add to them, mostly of the genera *Ulex* and *Genista*, as well as some grasses, bulbs, mosses and lichens. Heathlands are particularly frequent in the western part of Europe where they encompass both its northern and southern extremes, being also found in many areas of the center of the continent. In many European territories they play an important role in the landscape, where they occupy a substantial share of the surface. Depending on the dominant shrub species and the treatment, heathlands size can vary from a mid-sized shrubland up to 2 m dominated by gorses (*Ulex* species) to a dwarf scrub of a few centimeters high rich in cryptogams and grasses. More frequently they adopt an intermediate size between 20 and 80 cm in a dense formation of woody ericoid plants covering large parts of the soil surface.

Soils

Typical heathlands grow on a range from dry, well-drained acidic and oligotrophic soils on ridges and slopes and sandy plains to moderately hydromorphic or slightly peaty soils in poorly-drained depressions prone to water accumulation. The ericaceous vegetation causes acidification and even podsolization in the soil. This is due to the acidity of its organic matter and the humidity of the climate which induces several processes in the upper layers of the soil profile: the formation of organic-mineral complexes of iron and aluminum oxides with the acidic compounds from the organic matter known as chelates. These chelates are leached and transported to deeper horizons (illuvial), where they accumulate. This loss of organic-mineral complexes eventually results in a bleached ash-gray color eluvial horizon which is rich in quartz, depending on bedrock and climate conditions. This edaphic process is known as podsolization and can end in the formation of true podzols derived by degeneration of brown soils (Fig. 1), but similar to those originated under the boreal conifer forest (Gimingham, 1972). Usually heaths are found on siliceous rocks such as granite, schists,

Fig. 1 Podzolic soil under a heathland in the Basque Country, northern Spain. (J. Loidi).

slate, sandstone or even sand dunes. In some cases, if the rainfall is high enough, cation weathering is so active that they can thrive even on base-rich bedrocks. Basiphilous heaths in such environments have a high number of calcicolous species and are classified in different plant communities than the genuine acidic heaths, and are dominated by species like *Erica vagans*.

Climate

Heathlands mostly are distributed in the Atlantic countries of Europe, where oceanic climate conditions prevail. They expand inland to some regions of central Europe under sub-Atlantic conditions, where they require a high moisture provision. In the north, under a long winter season climate, the short summer is cool and rainy and the vegetation does not experience any shortage of water. Southwards, summer becomes longer and warmer and even in winter vegetative activity is not suppressed. Such conditions demand more rain to sufficiently provide water the heather species require. For that reason, heathlands refuge in wet mountain slopes in west and southwest Iberia, as well as in their most southern part of their distribution range, in the highly rainy western slopes of the Rif range in north Morocco.

Ecology, Typology of the Communities Flora and Fauna

With the exception of topographic positions in which soils are shallow and rocky, impeding succession toward the establishment of a forests, such as coastal cliffs and mountain ridges, the great majority of the heathlands of Europe are intermediate steps in the successional series ending in the Potential Natural Vegetation (Fagúndez, 2012), i.e. seral stages of degradation of ancient forests (Fig. 2). They are strongly related to a severe and recurrent disturbance regime responsible for arresting the natural succession. Such disturbance regime consist fundamentally in burning, mowing and/or grazing, thus, most of the today existing heaths are secondary (Webb, 1998). Exceptions are primary stands on coastal cliffs and on windswept plateaus and ridges of mountains, especially in the boreal region.

Heathlands are found all along the western edge of the European continent, from North Cape to the Gibraltar strait, in all areas influenced by the ocean (Fig. 3); this includes Norway, western Sweden, Denmark, NW Germany, Benelux, France, Ireland, the United Kingdom, north and western Iberia and NW Morocco. In the interior areas of the European continent, i.e. central and eastern France, Germany, Poland, Czech Republic, the Alps, and the Carpathians, impoverished or subalpine versions of the heathlands are found on siliceous bedrock. Heathlands have a basic set of species which are present in most of its range and of its variants: *Avenella flexuosa*, *Calluna vulgaris*, *Carex pilulifera*, *Festuca* sp. pl., *Juniperus communis*, *Potentilla erecta*, *Pteridium aquilinum*, *Solidago virgaurea*, *Vaccinium myrtillus*, and some others. Such a broad geographic scope entails a strong diversification into several main subtypes. The following typology reflects the main vegetation synthesis have been published for Europe or its Atlantic countries (Böcher, 1940, 1943; Díaz González, 1998; Géhu, 1975; Mucina et al., 2016; Rivas-Martínez, 1979).

1. The first subtype corresponds to the boreal areas and subalpine-alpine levels of the temperate mountains and is submitted to relatively cold climatic conditions. It is extended in arctic-boreal regions and the subalpine belts of the European mountains (Pyrenees, Alps, Carpathians, Balkans) and is characterized mostly by cold-adapted species such as *Arctostaphylos uva-ursi*,

Fig. 2 Heathland on siliceous bedrock in Asturias, northern Spain. (J. Loidi).

Arctostaphylos alpinus, *Bruckenthalia spiculifolia*, *Empetrum hermaphroditum*, *Erica carnea*, *Loiseleuria procumbens*, *Rhododendron ferrugineum*, *Rhododendron hirsutum*, *Rhododendron myrtifolium* and *Vaccinium gaultherioides*, while more widespread ericoid species like *Calluna vulgaris*, *Erica cinerea*, *Vaccinium myrtilis* and *Vaccinium vitis-idaea* may dominate as well. They are natural and semi-natural acidophilous close stands of dwarf-shrub heaths, mostly on siliceous bedrock, sometimes on neutral or base-rich soils. These heaths are usually dominated by one or few heathers and are quite species-poor in terms of vascular plants, in which representatives of the *Ericaceae* and *Empetraceae* families play an important role. The plant diversity is mainly found in mosses and lichens. *Hylocomium splendens* is a typical moss species that may dominate, while many *Cladonia* and *Cetraria*-species may form a lichen-rich moss layer. There are substantial differences in the floristic composition between the northern areas (boreal-arctic) and the subalpine-alpine levels of the southern mountains. In the temperate mountains, *Rhododendron*-heaths occupy sheltered sites with deep long-lasting snow cover, while *Loiseleuria*-heaths are found on snow-free ridges, exposed to the severe cold of the winter. In the boreal region, *Arctostaphylos* and *Vaccinium* grow on more sheltered or lower sites, while the moss *Racomitrium lanuginosum* may dominate the highest and most windswept areas. Such differences are the result of the higher amount of snow in subalpine-alpine areas in comparison to the boreal region and in different conditions during summer, with long and cold nights in the subalpine-alpine areas in contrast to the almost permanent daylight of the boreal-arctic growing season. This variant is mainly classified within the class *Loiseleurio-Vaccinieta* for arctic-boreal tundra dwarf shrubland and alpine acidophilous heaths and *Vaccinio-Piceetea* for the subalpine and boreal heaths. Information about this type can be found in Rodwell (1991), Fremstad (1997), Delarze and Gonseth (2008), and Čarni and Šibik (2016).

2. A second subtype is the northern and central-European heath, submitted to a climate with cold winters due to latitude or to continentality. Its vascular plant flora is relatively poor in comparison to the southern heathlands: we can only mention *Empetrum nigrum* (for north Europe), *Genista germanica*, *Genista pilosa* and the rare *Diphysastrum tristachyum* as characteristic species, while *Calluna vulgaris* and *Vaccinium* species are common shrubs, substituted by *Erica tetralix* in younger stages. Also here, the main diversity consists of mosses and lichens, and one can see a shift in species-composition of these cryptogams during succession. A specific variety are the very open, young *Calluna*-heathlands on inland sand dunes. They are found in large open, drift-sand areas, the so-called Atlantic deserts, which are the result of degradation of the landscape in historical times. These young heathlands are rich in lichens, especially of the genera *Cetraria*, *Cladina*, *Cladonia* and *Stereocaulon*. Older stages, especially in *Empetrum nigrum* dominated heaths, can be rich in large foliose hepatics of the genera *Barbilophozia*, *Lophozia*, and *Bazzania*, the later especially on loess. These northern and central heathlands inhabit the subatlantic and continental territories of western Europe, ranging from the northern foothills of the Pyrenees, central-eastern France, Germany, till the Alps and Bohemia and expanding northwards to the British Isles, the Benelux, NW Germany, Denmark and southern Norway (Böcher, 1943; Nordhagen, 1921). The alliances *Empetrium nigri* (restricted to coastal dunes), *Calluno-Genistion pilosae* and *Genisto pilosae-Vaccinion* group these heaths. Information about this type can be found in Rodwell (1991), Fremstad (1997), and Janssen (2016a).
3. A third subtype is the western Atlantic heath with *Ericaceae* and gorses spread across NW Iberia, western France and the western part of the British Isles. The characteristic species of this subtype are *Agrostis curtisii*, *Avenula marginata* subsp. *sulcata*, *Carex asturica*, *Daboecia cantabrica* (Fig. 4) *Euphorbia polygalifolia*, *Glandora prostrata*, *Halimium lasianthum*, *Erica cinerea* (Fig. 5A and B), *Erica mackaiana*, *Erica scoparia*, *Erica vagans* (Fig. 6), *Ulex europaeus* (Fig. 7), *Ulex gallii*, *Ulex minor*, *Pseudarrhenatherum longifolium*, *Simethis mattiazzi*, *Viola lactea*, *Xolantha globulariifolia*, among others. Most of these characteristic plants are restricted to the southern section of the territory. Going northwards, the floristic composition impoverishes significantly. Information about this type can be found in Géhu (1975), Géhu and Géhu-Franck (1975), Loidi et al. (1997), and Rivas-Martínez (1979).

Fig. 5 (A). *Erica cinerea* (J. Loidi). (B). *Erica cinerea* (J. Loidi).

Fig. 6 *Erica vagans* (J. Loidi).

4. A fourth subtype is the wet heath which appears in depressions where water accumulates and remains there for most of the year, giving way to a clear hydromorphy accompanied by low pH. They are represented in many regions of western Europe, from the Baltic countries to SW Iberia (Doñana), being particularly frequent in the wettest parts of the range: Northwest-Iberia, Ireland and the United Kingdom. The most indicative plants of this variant are *Erica ciliaris* (Fig. 8) and *Erica tetralix* (Fig. 9), which use to be accompanied by other hydrophilic plants such as *Carex panicea*, *Drosera rotundifolia*, *Juncus squarrosus*, *Gentiana pneumonanthe*, *Lycopodiella inundata*, *Molinia caerulea*, *Myrica gale*, *Narthecium ossifragum*, *Sphagnum compactum*, *Sphagnum molle*, *Sphagnum tenellum*, and *Trichophorum cespitosum* among others. In the edges of ponds of oligotrophic waters some wet grassland species appear in the heath, such as *Dactylorhiza maculata*, *Molinia caerulea* and *Pedicularis sylvatica*. In the warmer and more oceanic areas of the south Atlantic, particularly Iberia, *Cirsium filipendulum*, *Cirsium welwistchii*, *Euphorbia uliginosa*, *Genista ancistrocarpa*, *Genista anglica*, *Genista berberidea*, *Genista micrantha* and *Thymelaea coridifolia* subsp. *dendrobryum* characterize these wet heaths. The alliance *Ulici-Ericion ciliaris* includes these wet heaths, although Iberian stands have been grouped into the *Genistion micrantho-anglicae*. In the northern areas of Europe there are also *Erica tetralix* and *Calluna vulgaris* dominated fens, grouped in the *Ericion tetralicis* alliance. Information about this type can be found in Rodwell (1991) and Janssen (2016b).
5. A fifth subtype is formed by the coastal cliffs heaths (Fig. 10) of the Atlantic shores between NW Iberia and the British Isles (Fernández Prieto and Loidi, 1984). They are influenced by the saline spray of the sea wind and consequently several forms of wind-adapted cushion-shaped gorses and heathers dominate in the scrub, such as of *Ulex europaeus* f. *humilis* and *Ulex gallii* f. *humilis*. Plants adapted to salinity such as *Angelica pachycarpa*, *Anthyllis vulneraria* subsp. *iberica*, *Dactylis marina*, *Daucus carota* subsp. *gummifer*, *Festuca rubra* subsp. *pruinosa*, *Leucanthemum vulgare* subsp. *crassifolium*, *Plantago maritima*, *Pulicaria odora*, *Rumex acetosa* subsp. *biformis* or, *Silene uniflora*, are common in the vegetation, in addition to the common *Calluna vulgaris*, *Erica cinerea*, *Erica vagans* and *Glandora prostrata*. These coastal cliff heaths are considered as permanent communities, because succession is prevented by the saline and windy conditions. For that reason, they could be some of the primary stations of all the Atlantic European heaths, which survived during the cold phases of the ice-ages and existed before humans expanded heathlands since

Fig. 7 *Ulex europaeus* (J. Loidi).

Fig. 8 *Erica ciliaris* (J. Loidi).

the early Neolithic times by means of their land-managing procedures (Gimingham, 1972). Information about this type can be found in Fernández Prieto and Loidi (1984), Rodwell (1991), and Janssen (2016a).

6. A sixth subtype is the southern Atlantic heaths are widespread in W-SW Iberia (and actually reaching NW Morocco, Deil, 1984), inside the Mediterranean region (Fig. 11). They are found on the wet slopes of hills and mountains and on sandy humid depressions in the dunes and palaeodunes of the coastal strip. Climatically they thrive under conditions of severe summer drought but the high windward precipitations or the edaphic water table offset this shortage and this highly water-demanding vegetation can survive. This influence is shown by a high number of characteristic plants with a Mediterranean distribution: *Cistus crispus*, *Cistus psilosepalus*, *Cistus salviifolius*, *Drosophyllum lusitanicum*, *Erica andevalensis*, *Erica australis* (Fig. 12), *Erica scoparia*, *Erica umbellata*, *Genista triacanthos*, *Genista tridens*, *Glandora lusitanica*, *Halimium umbellatum*, *Halimium ocymoides*, *Hypericum linariifolium*, *Lavandula viridis*, *Luzula lactea*, *Polygala microphylla*, *Pterospertum tridentatum*, *Stauracanthus boivinii*, *Thymelaea broteriana*, *Thymelaea villosa*, *Thymus villosus*, *Ulex airiensis*, *Ulex jussiaei*, *Ulex micranthus*, and some others. In some areas where fire

Fig. 9 *Erica tetralix* (J. Loidi).

Fig. 10 A coastal cliff heathland (J.A. Campos).

and soil degradation is very intense, stands of *Cistus ladanifer* and *Cistus populifolius* can appear in the heathlands. Information about this type can be found in [Janssen \(2016a\)](#).

7. A particular subtype of European heathlands are those from the Azores Islands ([Lüpnitz, 1975](#)). They inhabit in the mid and high-elevation areas of the archipelago's volcanoes where the almost permanent fog soaks the vegetation constantly. A number of Macaronesian endemics, such as *Daboecia azorica* ([Fig. 13](#)), *Diphasiastrum maderense*, *Huperzia dentata* or *Huperzia suberecta*, together with *Calluna vulgaris*, form these heathlands. Information about this type can be found in [Capelo \(2016\)](#).

Fauna

For fauna species most heathlands are an extreme and dynamic environment, with strong fluctuations in temperature and water supply and limited availability of nutrients. The larger fauna usually operates on a landscape scale, and characteristic species in

Fig. 11 A western Iberian heathland (J. Loidi).

Fig. 12 *Erica australis* subsp. *aragonensis* (J. Loidi).

heathlands may prefer mosaics with open soil, grassland, tall-herb vegetation and forest. Typical birds related to such heathland landscapes are among others Black Grouse (*Tetrao tetrix*), Common Stonechat (*Saxicola rubicola*), Dartford Warbler (*Sylvia undata*), European Curlew (*Numenius arquata*), European Golden Plover (*Pluvialis apricaria*), Northern Wheatear (*Oenanthe oenanthe*), Whinchat (*Saxicola rubetra*) and Wood lark (*Lullula arborea*). The European Nightjar (*Caprimulgus europaeus*) is a ground breeder of the transition zone between forest and heathlands. Smaller animals often prefer a mosaic of different vegetation structures within the heathlands, and in many cases they require different (micro)habitats in different life stages. Typical reptiles are among others Slowworm (*Anguis fragilis*), Viviparous lizard (*Zootoca vivipara*), Sand lizard (*Lacerta agilis*), Smooth snake (*Coronella austriaca*), and in wet heathland Common European viper (*Vipera berus*). Amphibians are always related to wet heathlands or fens within the heathland landscape, including the Moor frog (*Rana arvalis*) and Natterjack Toad (*Epidalea calamita*).

The highest diversity of insects seems to be related with diversity in vegetation structure rather than in species diversity (Usher, 1992; Stuijzand et al., 2004), although some species depend on one plant species or genus in their larval stage. Many butterflies, spiders, grasshoppers, beetles, wasps, bees and ants have concentrations of their distribution in heathland areas. Some examples are the butterflies Silver-studded Blue (*Plebejus argus*), Green Hairstreak (*Callophrys rubi*), Grayling (*Hipparchia semele*), Silver-spotted Skipper (*Hesperia comma*), Tree Grayling (*Hipparchia statilinus*), Grizzled Skipper (*Pyrgus malvae*) and—characteristic for wet heathlands—Alcon Blue (*Phengaris alcon*), which larvae live on *Gentiana pneumonanthe*. In the Alps Asian Fritillary (*Hypodryas intermedia*) is characteristic, while in subalpine and boreal heathlands Cranberry blue (*Plebeius optilete*) is a typical butterfly species. Among the

Fig. 13 *Daboecia azorica* (P. Arsenio).

grasshoppers we mention Wart-biter (*Decticus verrucivorus*), Heath-bush Cricket (*Gampsocleis glabra*), Blue-winged Grasshopper (*Oedipoda caerulescens*) and the Field Cricket (*Gryllus campestris*). It is also worth mentioning the ground beetle *Callisthenes reticulatus* which lives in the west European heathlands. A last species that should be mentioned in particular is the Heather Beetle (*Lochmaea suturalis*). Both larvae and adults eat heather (leaves, stem apices and bark) and cause regular outbreaks that may destroy entire dry heath patches (Gillingham et al., 2015). The beetle occurs in the dry *Calluna* dominated heaths of Western Europe.

Biogeography and Biodiversity Patterns

The biodiversity of European heathland is expressed by the variety in subtypes described above, and these subtypes show clear patterns of geographic distribution of their plant species and communities. These patterns can be explained by the history of the Quaternary and its climatic oscillations on one hand (Loidi et al., 2010), and by the history of the human influence during the Holocene, on the other hand.

Concerning the origin of the flora of the European heathlands, we can distinguish two sets: one is formed by species that were differentiated by adaptation to a cold climate, the Arctic-Boreal set, and the second by species that were differentiated by being adapted to a warm-temperate to subtropical rainy climate. The former was likely formed during the Pleistocene when the temperatures experienced dramatic descents in the high and mid latitudes. The latter is an older group, probably differentiated along the Tertiary in an area now including NW Iberia, the Gulf of Biscay and surrounding territories. Several phylogeographic surveys carried out so far and the current distribution of the heathland species are in favor of this hypothesis (Gil-López et al., 2017; Hornoy et al., 2013; Mahy et al., 1999). The small group of species with mainly a boreal and alpine distribution are the characteristic plants for the first subtype of our classification. The “subtropical” species are clearly concentrated in Iberia, where they likely originated and diversified and later refuged during the ice-ages, as is documented for heathers, gorses and other taxa. This group has a broad representation in the Atlantic areas, such as western France and the British Isles, where some of the heathers show a significant disjunct distribution, as is the case for *Daboecia cantabrica* (Beatty and Provan, 2013) and *Erica mackaiana*. The subtropical group constitutes the floristic core of these European heathlands, which has expanded over the northern and central European territories during the warm phases of the Pleistocene and during the Holocene.

The Azores archipelago rose from the ocean bottom (Azores Platform) due to volcanic activity and reached the sea surface in a period when the Atlantic Ocean was substantially narrower than it is now. The first island, Santa María, emerged about 8.12 million years ago. Thus, Europe, now at a distance of 480 km, was likely closer to the archipelago than it is now. That means that the heathers that occurred in SW Europe could colonize this archipelago creating a back and forth migratory relationship helped

by a system of “stepping stone islands” (Fernández-Palacios et al., 2011). Later, the Azores became more isolated due to the separation of Europe from North America, driven by the plate tectonics and, due to this isolation, the flora differentiated, having a large set of endemic plants.

The other driver explaining current distribution patterns of heathlands across Europe is human intervention. Land use has functioned only as a driving force since early to mid Holocene (8000–6000 years ago), when Neolithic cultures, with agriculture and animal husbandry, spread over Europe. Such activities have a high impact on vegetation and in a traditional way of land use, they intensely favor the expansion of heathlands. For that reason, many of the current heaths are considered anthropogenic and likely many regions in Europe were invaded by heathlands due to human land use, particularly in areas with siliceous bedrock.

Natural vs. Anthropogenic Communities

For a long time it was thought that heathland has always existed as the landscape we know today. However, insights from land-use history, archeology, palynology and vegetation science completed our understanding of the processes that determine occurrence and development of the current plant communities.

In Norway, the lowland heath region along the west coast was completely forested until 5000 years BP (Kvamme et al., 2004). From then on, small-scale forest clearance started and continued for more than 4000 years. Pollen analyses made clear that the reduction of the tree cover was accompanied by the establishment and increase of a *Calluna* dominated heath vegetation plus an increase of peat formation. The existence of charcoal remnants at the stratigraphical border between forest and heather peat and of charcoal dust in all the subsequent layers, strengthen the arguments that the development and spread of lowland heath was induced by man, mainly by intentional burning (Kaland, 1986).

On the British Isles a comparable evolution took place. Changes in the pollen signature of peat and in soil development (podsolization) make clear that from the Atlantic period on, when the climate became more oceanic, the impact of man on the landscape became prominent. The original forest cover was disturbed, leading to the spread of heathland which was encouraged by the increased leaching of the soils that followed the deforestation. At the Late Bronze age (3000 BP) heathlands extended to become a dominant land cover over in major parts of the British Isles (Rackham, 1997; Webb, 1986).

In the Iberian Peninsula similar palynological observations have been made. The expanse of *Calluna vulgaris* and *Erica* species coincided with evidence of extended grazing areas, originated from severe fires (for instance Abel-Schaad et al., 2014). Frequent severe fires hindered the complete recovery of forests while shrubland and grasslands established. From 5800 to 5400 BP on, heathlands developed and became the dominant vegetation type in vast areas with suitable soil and climatic conditions. They were maintained by fires, most likely associated with human activities (Morales-Molino et al., 2013). There are plenty of evidences showing that forest vegetation preceded heaths almost universally and that human settlements and land cultivation and grazing frequently are associated with the decline of forest and increase of heath (Gimingham, 1972). Human induced disturbance regimes that created most of the European heathlands have persisted so far.

Although rapid re-growth of forest after clearance was prevented because of all-year-round grazing of heath, made possible by the oceanic climate and because of the harsh environmental conditions, agriculture in the Atlantic domain of Western Europe had to cope for thousands of years with the same environmental constraints (Gimingham and de Smidt, 1983; Webb, 1986). This resulted in a comparable landscape pattern from the Lofoten Islands in Norway to the Serra da Estrêla in Portugal (Haaland, 2002). The solutions and techniques used to overcome the natural factors that limited production in these regions, gave rise to the same organization and use of the land: a combination of large ‘outfields’ -the heathlands- and ‘infields’ -the cultivated land- (Webb, 1998). Management of the outfields had the purpose of maintaining and optimizing them as a crucial source in the local agricultural economy (De Blust, 2007; Diemont et al., 2013). The outfields served as grazing land for horses, cattle, goats and sheep, which were crucial natural resources on the farm, not least as producers of manure and other valuable products that could be marketed. To ensure a sufficient quality and quantity of fodder for grazing animals, the main management of these outfields was to burn them regularly (Niemeyer, 2005). *Ulex* and *Sarothamnus* were harvested for an additional valuable fodder. Cut *Calluna* and turfs served as bedding in the stables and, saturated with manure, became valuable fertilizers for the permanent infields. In some regions, fertilization of temporary fields was achieved by sowing *Sarothamnus*. In the Ardennes (Belgium) and in Brittany (France), after collecting the useful fodder and bedding, the remaining dried litter and crumbled humus layer was submitted to controlled burning and the ashes and clay were spread over the parcel of former heath to provide a new, temporary field for rye and buckwheat. This was the practice of ‘écobuage.’ All these uses of the heathland, resulted in a continuous flux of minerals and energy, from the outfields to the infields, a key process that this farming system and the landscape depended on (Haaland, 2002).

400–200 years ago, lowland heath was at its greatest extent in Europe. In many places however, despite strong traditions and regulations (De Moor et al., 2002), exploitation had reached and surpassed the limits of sustainability. Productivity fell to a minimum and in sandy regions shifting dunes expanded and threatened farms and covered the heath. The decline and transformation of heathland was inevitable when in the 18th century changing economic conditions, improved technology, population growth and the interests of foreign rulers, challenged its traditional use and functions. Heath no longer fitted with the ever-growing human society and it was cultivated as permanent agricultural land, planted with pine or *Eucalyptus* forest, reclaimed for urbanization or made productive for the emerging industries.

Threats

The area of heathland that has remained until today, is only rarely still part of the current (local) agricultural system. This has huge consequences for the functioning of this ecosystem. In former days, the agricultural use led to a continuous flux of energy and minerals out of the heath which resulted in an impoverishment of the system. Today, because of the cessation of traditional management, and especially because of the substantial increase of atmospheric deposition, the flow is inverted and nutrients accumulate (Terry et al., 2004). As a result, natural succession toward forest is not hindered by intensive grazing or other management interventions anymore and altered environmental conditions facilitate potentially dominant plant species, especially grasses, to rapidly spread and become dominant in the vegetation (Aerts and Heil, 1993). Development toward more homogeneous and grass dominated vegetation is further intensified by desiccation of the wet heath due to drainage and ground water pumping activities. This favors the mineralization of the organic soil layer which leads to increased nutrient availability. Species dependent on groundwater are becoming increasingly rare and species richness of communities decreases. Finally, in large parts of Europe changes in pH have affected the heathland ecosystems in various ways; by altering the balance and availability of minerals in the soil and water, by causing direct toxic or lethal effects, and by hindering successful reproduction and seedling establishment. Again, some species become extinct while others find favorable conditions to spread, or even may invade the heathland communities.

Where heathlands became part of nature reserves the management changed as well. More large-scale grazing, burning and sod-cutting resulted in a more homogeneous vegetation structure, and this is especially problematic for the insect and reptile fauna of heathlands. Besides, atmospheric deposition causes soil acidification and eutrophication, which alter the mineral balance (high nitrogen amounts, low concentrations of Calcium and other elements)—resulting in lower food quality for fauna (Vogels et al., 2013)—and stimulate the dominance of grasses—resulting in reduction of bare soil and lowering of vegetation structure diversity. Together with fragmentation of remaining heathland patches, these are the main causes for many characteristic animal and plant species in heathlands to be endangered. In areas with high amounts of atmospheric deposition, sod cutting has been a management practices since the 1980s, aiming at removing nutrients and dominance of grasses. However, the large scale at which this management has been practiced, has resulted in a low proportion of heathlands with undisturbed humus profiles. Especially such older and more stratified soils have better water and buffer capacity, and need conservation from that perspective (Bijlsma et al., 2013). One of the unwanted by-effects of large-scale sod-cutting is the loss of foliose hepatics which are dependent on undisturbed humus profiles. Since their dissemination abilities are poor, the recolonisation of heathlands is hampered once they disappeared.

Fagúndez (2012) deals about the dynamics of heathlands identifying 5 drivers of change which operate at different scales and have diverse prevalence and intensity. In order of the importance of their currently visible effects we could quote: (1) Habitat destruction and fragmentation due to land use change; (2) Natural vegetation dynamics enhanced by rural abandonment; (3) Air pollution and eutrophication mostly by atmospheric N deposition; (4) Climate change with temperature increases and changes in precipitation amount and distribution; (5) The spread of invasive exotic species. These drivers interact among themselves and make up a summary scheme of elements and relationships that determine the changes experienced by heaths today.

Conservation, Restoration and Sustainable Management

Heathlands have received a great attention from the European Union in its nature law, the Habitats Directive (EU, 2013), as a logical consequence of the multiple pressures which lead to a decrease in their abundance and diversity. There are eight habitat types which are included in Annex 1 of that Directive, three of them of priority conservation (*): Dry sand heaths with *Calluna* and *Genista* (2310), Dry sand heaths with *Calluna* and *Empetrum nigrum* (2320), Northern Atlantic wet heaths with *Erica tetralix* (4010), Temperate Atlantic wet heaths with *Erica ciliaris* and *Erica tetralix* (4020*), European dry heaths (4030), Dry Atlantic coastal heaths with *Erica vagans* (4040*), Endemic macaronesian heaths (4050*), and Alpine and Boreal heaths (4060). As the majority of these heathlands are secondary and linked to human management, their conservation is only guaranteed by maintaining the traditional exploitation regime that prevents succession toward forest. Some type of disturbance has to be applied: mowing, grazing, burning or a similar management which keeps the vegetation in a scrub state (Figs. 14 and 15). Prescribed and controlled fires following a low frequency temporal pattern is a reasonable and low cost option when no other actions can be taken. Currently a European Dry Heath Action Plan is under development, initiated by the European Union.

It is however important to carry out management practices at a small scale, whenever possible within financial, social and practical prerequisites, as large-scale management leads to homogeneity in vegetation structure and micro-climates, and this causes loss of flora and fauna diversity. One should be aware that in the sandy plains of Northwestern Europe, historically, the heathlands on more productive soils have been transformed into agricultural land in an early stage and at a much larger scale, leaving behind mainly heathlands on very poor soils. Especially on such soils, atmospheric deposition is a huge problem, and no solution has been found yet to alter the misbalance between nutrients and loss of minerals. At an experimental scale, the addition of rock dust has been applied, aiming at restoring the balance of minerals in the soil and plants.

Abstract

Shrublands are largely represented in Europe being diversified into several types. They are found in primary stations, usually on shallow soil sites of rocky places and steep slopes, in which they were differentiated along history and evolution. However, the overwhelming majority of the currently existing shrublands are in secondary stations, as seral stages of forests, being favored by humans by means of the traditional land use systems, particularly extensive husbandry and farming. They often form hedgerows for fencing rural properties, most of them by spiny shrubs such as brambles, roses and blackthorns. This vegetation produces abundant organic matter and keeps the soil in good conditions of fertility. Shrublands also host a large number of small animals, particularly butterflies, and provide abundant fleshy fruits for seed dispersal which fodder many birds. The conservation of the reticulated hedgerows landscape, known as bocage, is a relevant issue for the preservation of the structural complexity and biodiversity of the terrestrial ecosystems in temperate Europe. The modern tendency towards more technological exploitation systems in some regions, parallel to the rural abandonment in others, is leading to the reduction of this habitat type all over Europe.

Delimitation and Physiogeography of the Region

In the progressive succession towards the forests starting from abandoned fields, grasslands or heathlands, there is a stage formed by shrubs which precedes mature forest. They represent the previous stage before the potential natural vegetation, which is a summergreen deciduous forest in most of the European territories under a temperate climate. These shrublands replace forests after disturbance, whereas in stable disturbance-free situations, they also constitute their edge communities. The forest patches are surrounded by a linear fringe of shrub sealing them and, for that reason, they are often called mantel or forest-edge communities. By sealing the border of the forest patch, the conditions proper of the forests ecosystem (shade, temperature, humidity and a tempered wind), are preserved. In addition to this secondary position as seral stages and forests edges, shrublands have a primary position in rocky places with shallow soils unable to sustain true forests, such as crests, ridges and steep slopes. Also in severe wind exposed sites or under very dry or very wet conditions, where trees are unable to grow, shrubland may form the potential vegetation.

Mantel shrubs produce a high amount of organic matter which is usually easy degradable (mull) and to intermingle with the mineral fraction, being able to keep the soils built under the forest in good conditions of depth and fertility. This is an important point as regards their appraisal for conservation, particularly in areas where soil degradation is a threat. In the Mediterranean they are replaced by macchia or garrigue, in the north and in the upper altitudinal belts in the mountains by cold adapted heathlands.

Ecology and Biodiversity Patterns; Typology of the Communities, Flora And Fauna

The vegetation is formed by shrubs of diverse size, from humble scrubs of a few tens of centimeters, to small trees like hazel or dwarf forms of hornbeams or cherry trees. Many shrub species are spiny and have fleshy fruits adapted to animal dispersal—endozoochory- (Fig. 1). Especially in the Mediterranean, leafless woody legumes with green photosynthetic stems dominate, having the ability to fix atmospheric nitrogen, thus enhancing the fertility of poor soils.

Temperate forests are considered the climax or potential natural vegetation in most of Europe, representing the ecosystem optimum in terms of naturalness and complexity, but shrublands, which usually are a subordinate vegetation type, have important features referring the forest, particularly due to their capacity to build structured soils and to cast intense shade on the soil surface. In forest edges, where shrublands form a transition from grassland to forest (Fig. 2), these mantles may be very species rich, combining species of both the open and the wooded habitats, apart from the edge specialists. In the form of hedgerows, the combination of species preferring shady conditions and sunny conditions may also cause high diversity. Shrublands also harbor

Fig. 1 Blackthorn (*Prunus spinosa*) fleshy fruits (J.Loidi).

Fig. 2 The edge of the forest is sealed by a thorny species shrub mantle (J.Loidi).

many (apomictic) micro-species of plants, especially within the family of *Rosaceae*, like in the genera *Rubus* (Fig. 3), *Rosa* and *Crataegus*. These micro-species contribute largely to the plant diversity in temperate regions.

We can distinguish eight main subtypes of this vegetation in temperate Europe.

1. Deciduous spiny shrubland. The most extensive subtype is that of the deciduous -often spiny- shrublands. They are found over deep soils with medium to high fertility and nutrient richness. They are related to the temperate summergreen deciduous broadleaved forests of the class *Querc-Fagetea*. Very frequently, these shrublands are formed by thorny shrubs of the *Rosaceae* family, with the genera *Amelanchier*, *Crataegus*, *Prunus*, *Pyrus*, *Rosa* (Fig. 4), *Rubus*, etc. being largely represented. Other genera are *Berberis*, *Cornus*, *Corylus*, *Euonymus*, *Ligustrum*, *Rhamnus*, *Ribes*, *Ulmus*, *Viburnum*, etc. Due to their spinosity, these shrublands have been transformed into living semi-natural hedges separating rural parcels (Fig. 5) and bordering countryside roads. In addition to its impenetrability, they shelter many small vertebrates and insects, many of them pollinators of plants of the neighboring lands often crops or meadows. Additionally, the fleshy fruits, abundant from late summer to early winter, provide an important resource for many animal populations, especially birds. Both the hedges and the forest edges form important migration routes for different groups of animals, like small mammals, bats and butterflies. Besides, hedgerows function as corridors between different forests patches for such species, especially in fragmented landscapes. the typical European farmland landscape of the "bocage" (a french term for a landscape in which hedgerows are a characteristic feature) is the paradigm of the use of these spiny shrubs to build a linear grid of hedges that frames and includes meadows and fields. The most common and characteristic species of these spiny shrublands are: *Acer campestre*, *Acer monspessulanum*, *Acer tatarica*, *Amelanchier ovalis*, *Berberis aetnensis*, *Berberis hispanica*, *Berberis vulgaris* subsp. *cantabrica*, *Berberis vulgaris* subsp. *vulgaris*, *Cornus mas*, *Cornus sanguinea*, *Corylus avellana*, *Corylus colurna*, *Cotinus coggygria*, *Cotoneaster granatensis*, *Cotoneaster integerrimus*, *Cotoneaster nebrodensis*, *Cotoneaster tomentosus*, *Crataegus granatensis*, *Crataegus laciniata*, *Crataegus laevigatus*, *Crataegus monogyna*, *Crataegus orientalis*, *Crataegus transalpina*,

Fig. 3 Bramble (*Rubus ulmifolius*) flower (J.Loidi).

Fig. 4 Wilde rose (*Rosa canina*) flower (J.Loidi).

Euonymus europaeus, *Euonymus verrucosus*, *Hippophae rhamnoides*, *Ligustrum vulgare*, *Paliurus spina-christi*, *Prunus avium*, *Prunus institia*, *Prunus mahaleb*, *Prunus ramburii*, *Prunus spinosa*, *Pyrus elaeagrifolia*, *Pyrus pyraster*, *Malus sylvestris*, *Rhamnus alpinus*, *Rhamnus catharticus*, *Rhamnus intermedia*, *Rhamnus saxatilis*, *Ribes alpinum*, *Ribes uva-crispa*, *Rosa agrestis*, *Rosa canina* agg., *Rosa dumalis*, *Rosa micrantha*, *Rosa montana*, *Rosa obtusifolia*, *Rosa pouzinii*, *Rosa pendulina*, *Rosa rubiginosa*, *Rosa sherardii*, *Rosa sicula*, *Rosa tomentosa*, *Rosa villosa*, *Rosa vosagiaca*, *Rubus bifrons*, *Rubus caesius*, *Rubus canescens*, *Rubus dalmaticus*, *Rubus egregius*, *Rubus elegantispinosus*, *Rubus geertii*, *Rubus geniculatus*, *Rubus grabowskii*, *Rubus lindleianus*, *Rubus macrophyllus*, *Rubus montanus*, *Rubus phyllostachys*, *Rubus polyanthemus*, *Rubus praecox*, *Rubus radula*, *Rubus raduloides*, *Rubus rubercadaver*, *Rubus rufescens*, *Rubus senticosus*, *Rubus steracanthos*, *Rubus ulmifolius*, *Rubus vestitus*, *Rubus wahlenbergii*, *Rubus winteri*, *Sambucus nigra*, *Sorbus aria*, *Syringa vulgaris*, *Viburnum lantana*, *Viburnum opulus*, etc. In the southern section of the area of this shrubland type, from Iberia to the Balkans, some evergreen species appear, such as *Buxus sempervirens*, *Phillyrea latifolia* or *Ruscus aculeatus*, combined with some submediterranean deciduous species: *Acer monspessulanum*, *Ostrya carpinifolia*, or *Quercus pubescens*. These shrublands may be distinguished as a submediterranean variety.

Thorny shrublands find their optimal area in temperate central-western Europe. Northwards, they lose most of the thermophilic species and become impoverished, whereas in continental areas of Europe most Atlantic taxa are missing. In the Mediterranean territories, they are represented by species-poor communities confined to riverbanks and to some mountain areas under a rainy climate, always on deep nutrient-rich soils.

Thorny shrublands are grouped into the class *Rhamno-Prunetea spinosae* (Tüxen, 1952, Arnaiz, 1983, Géhu et al., 1983, 2003, Weber, 1998, Bergmeier, 1990, Janssen, 2016b, Haveman and de Ronde, 2019).

2. Hazel calcareous scrub. A subtype (more-or-less) differentiated from the previous one is the *Corylus avellana* scrub. It comprises relatively stable shrublands dominated by hazel, growing basically on limestones in regions of temperate climate, from the British Isles to Central Europe, Central Italy and northern Spain. It establishes in situations where the shallow soils (crests, steep

Fig. 5 Hedgerow fencing a hay meadow (J.Loidi).

slopes), sometimes helped by strong winds, prevent the development of the forest. The associated species vary across the geographic range of this type, being mostly herbs typical of forests and grasslands. Grazing and browsing, usually by sheep or goats, open up the *Corylus* canopy and introduce more grassland species in the understory, preventing the regeneration of the hazel and other shrubs and trees. Under this management it is produced a kind of parkland in which old hazel individuals form a discontinuous canopy covering a shaded grassland. This is adapted to a pastoral exploitation system combined with the harvesting of the hazel branches and fruits (nuts), important items in the traditional rural economy. Under such management, the conservation of this shrubland type is ensured (Janssen, 2016c).

3. Atlantic bramble shrub. In Atlantic and sub-Atlantic regions of Europe a subtype of shrubland dominated by brambles (*Rubus* sp. pl.) is found in places under a cool microclimate on acidic soils submitted to intermediate moisture conditions. This vegetation includes bramble species-rich formations forming forests edges and extensive scrub in open landscapes, mostly on sandy soils, with a broader distribution in northwestern Europe and submontane areas in Central Europe (Central France-Germany-Bohemia-Poland). They are formed basically by *Rubus* species, many of them endemics such as *Rubus adpersus*, *Rubus amiantinus*, *Rubus ammobiis*, *Rubus bertramii*, *Rubus calvus*, *Rubus contractipes*, *Rubus discors*, *Rubus distractus*, *Rubus divaricatus*, *Rubus drenthicus*, *Rubus flexuosus*, *Rubus frederici*, *Rubus glandithyrus*, *Rubus gratus*, *Rubus integribasis*, *Rubus laciniatus*, *Rubus laevicaulis*, *Rubus lasiandrus*, *Rubus mucronulatus*, *Rubus mycrophyllus*, *Rubus nemoralis*, *Rubus nessensis*, *Rubus passionis*, *Rubus phoenicacanthus*, *Rubus plicatus*, *Rubus pyramidalis*, *Rubus scissus*, *Rubus schlechtendalii*, *Rubus silvaticus*, *Rubus sprengelii*, *Rubus taxandriae*, *Rubus trichanthus*, and *Rubus vigorosus* amongst others. These bramble scrubs are included in the class *Lonicero-Rubetea plicati*, alliance *Lonicero-Rubion silvatici* (Haveman et al., 1999; Weber, 1990, 1997, 2003; Janssen, 2016d; Haveman and de Ronde, 2019).
4. Forest gaps bramble shrub. In the colline and submontane belt (and rarely in the lowlands) of central and western Europe, another type of bramble-shrub is found, formed by low-growing, glandular, forest-dwelling *Rubus* species. This type occupies smaller or larger gaps in the forest-canopy (e.g. tree felling caused by storms) and is confined to humus-rich and not too nutrient-poor soils within the tempered microclimate of mainly broad-leaved forests of the class *Querceto-Fagetea*. Although they might facilitate tree-sapling establishment, there are examples that massive bramble-vegetation hampers the regeneration of the forest canopy. Species composition of these 'silvicolous' bramble-scrubs is yet poorly known, since they are recognized only recently. These 'silvicolous' bramble-shrubs are characterized by *Salix caprea*, *Sambucus racemosa*, and many (mainly only regionally distributed) bramble species, amongst which *Rubus bellardii*, *Rubus foliosus*, *Rubus hirtus*, *Rubus hypomalacus*, *Rubus idaeus*, *Rubus igoratus*, *Rubus iuvenis*, *Rubus loehrii*, *Rubus lusaticus*, *Rubus melamporphyrus*, *Rubus mucronipetalus*, *Rubus negatus*, *Rubus oreades*, *Rubus pallidifolius*, *Rubus pallidus*, *Rubus picearum*, *Rubus rosaceus*, *Rubus rudis*, *Rubus schleicheri*, *Rubus serpens*, *Rubus sulcatus* and *Rubus teretiusculus*. Phytosociologically, these scrubs are assigned to the alliance *Athyrio felicis-feminae-Rubion idaei* Passarge ex Haveman and De Ronde 2014, class *Rhamno-Prunetea spinosae* (Passarge, 1982; Haveman and de Ronde, 2014; Haveman et al., 2017c; Weber, 2003).
5. Steppic central-eastern scrub. There is a steppic low scrub occurring in central-east Europe centered in the Pannonian Basin and reaching Ukraine and Russia. It is a scrub of usually less than 1 m tall, common in the forest-steppe and steppe zones, developing on both shallow soils (leptosols) near rock outcrops and on deep soils (chernozems, kastanozems, phaeozems, cambisols or luvisols). Frequently it forms stands of clonally growing dominant shrubs on relatively mesic sites in relation with the dry grasslands. It also forms forests edges in form of tall scrub or dry woodland. In places with shallow soils it is a permanent natural vegetation type, while in others with deeper soils is a successional stage replacing the dry grassland after abandonment. The most

typical flora is formed by: *Caragana frutex*, *Cotoneaster integerrimus*, *C. melanocarpus*, *Elymus hispidus*, *Festuca rupicola*, *F. valesiaca*, *Fragaria viridis*, *Geranium sanguineum*, *Melica ciliata*, *M. transsilvanica*, *Poa angustifolia*, *Polygonatum odoratum*, *Prunus x eminens*, *Prunus fruticosa*, *Prunus tenella*, *Rosa gallica*, *Rosa pimpinellifolia* (= *R. spinosissima*), *Spiraea chamaedryfolia*, *Spiraea crenata*, *Spiraea media*, etc. These scrubs are gathered into the Alliance *Prunion fruticosae* Tx. 1952 (Tüxen, 1952; Chytrý, 2013; Doniță et al., 2005; Bită-Nicolae, 2016).

6. Western broom legume shrubland. A sixth subtype formed by leafless shrubby legumes (brooms) of the genera *Adenocarpus*, *Cytisus*, *Genista*, *Retama* and occasionally *Ulex*. These plants have photosynthetic stems and are very active in fixing atmospheric nitrogen. This evergreen vegetation, from 0.6 up to 3 m high, is the first seral stage and mantel of temperate forests of *Quercus pyrenaica*, *Q. robur*, *Q. petraea*, *Fagus sylvatica* being also represented in the domains of *Q. rotundifolia* and *Q. suber*, in part of the Mediterranean region, particularly in western Iberia (Fig. 6). The highest diversity and representation of these mantel shrublands are in W and NW Iberia, although there is an important penetration towards central and NW Europe by means of the *Cytisus scoparius* communities. In the area of its optimal development and diversity, they are mostly found on siliceous nutrient-poor and low pH substrates, replacing the thorny mantel of the previous subtypes that are more exigent in moisture and in soil nutrients. Due to its particular morphology, this scrub receives several names in Spain: piornal, escobonal or retamal, depending the geographic area and the dominance of one or other species. This vegetation is not so useful for the farmers to build efficient hedges because it is a non-thorny vegetation. For that reason it is very rare to find hedgerows made of them. However, it is very frequent to find it in form of scattered individuals covering extensive areas under agro-pastoral management in a pattern resulting from the specific and ancient model of human management. It is notorious to remark that shepherds know empirically that these plants “enrich” the soils and promote its fertility. For that they avoid a complete deletion of these communities in the grazing areas, even conserve a regularly scattered pattern of these retamoid individuals intermingled with the heathland or the grassland. Often the green branches and seeds of these species can be used as an additional fodder for the livestock in periods of shortage of available pasture. This shrubby broom-like vegetation easily catches fire and suffers from frequent burning in the areas where it is abundant. Fires, if repeated with high frequency, lead to the establishment of heathland, which is accompanied by soil degradation. A regime of frequent fires has been induced historically, to most of the present day heaths of western Iberia and Europe. If fires are not so frequent, broom shrublands, are resilient and recover in a few years without fire from the surviving roots or from seed, thanks to the high germination capacity of their seeds. Fire frequency determines whether heathland or shrubland is the dominant plant community in the landscape. The plant species of this subtype are: *Adenocarpus anisochilus*, *Adenocarpus argyrophyllus*, *Adenocarpus aureus* subsp. *aureus*, *Adenocarpus complicatus* (subsp. *brutius*, subsp. *complicatus*), *Adenocarpus decorticans*, *Adenocarpus hispanicus* (subsp. *gredensis*, subsp. *hispanicus*, subsp. *neilense*), *Adenocarpus lainzii*, *Adenocarpus telonensis*, *Cytisus cantabricus*, *Cytisus commutatus*, *Cytisus ingramii*, *Cytisus scoparius* (subsp. *scoparius*, subsp. *bourgaei*), *Cytisus grandiflorus* subsp. *cabezudo*, *Cytisus multiflorus*, *Cytisus striatus* (subsp. *eriocarpus*, subsp. *striatus*), *Echinopartum ibericum* subsp. *ibericum*, *Genista cinarescens*, *Genista cinerea* subsp. *speciosa*, *Genista florida* (subsp. *florida*—Fig. 7 and subsp. *polygaliphylla*), *Genista obtusiramea*, *Genista polyanthos*, *Orobancha rapum-genistae*, *Retama monosperma*, *Retama sphaerocarpa*, *Ulex europaeus* (subsp. *europaeus*, subsp. *latebracteatus*). The core of the broom genistoid shrublands is the Iberian Peninsula, from where it expands northwards and eastwards over large areas of western and central Europe until Denmark, Italy and Croatia. In this expansion, most of the species remain in Iberia and only *Cytisus scoparius*, *Ulex europaeus* and *Orobancha rapum-genistae* are broadly distributed on sandy or loamy soils. These shrublands are framed into the class *Cytisetea scopario-striati* widespread across

Fig. 6 Broom shrubland in central Spain (F. Fernández-González).

Fig. 7 *Genista florida* in central Spain (F. Fernández-González).

western Europe (Rivas-Martínez, 1974; Gavilán et al., 2011; Pinto-Gomes et al., 2012; De Foucault et al., 2013; Janssen, 2016a; Haveman et al., 2017b).

7. Atlantic coastal dune buckthorn shrub. Along the coast of north-western Europe, including the British Isles, France, Belgium, The Netherlands and Denmark, Sea-buckthorn forms pioneer shrublands on calcareous dune-sand, following *Ammophila* and dune grassland communities in the succession (Fig. 8). Both species can inhabit moist dune slacks as well as dry dune complexes. Like the species in the retamoid scrubs of the previous type, Sea-buckthorn is able to fixate atmospheric nitrogen, stimulating the soil development in this pristine environment. Natural soil acidification through leaching and infestation with nematodes

Fig. 8 *Hippophae rhamnoides* shrubland and grassland of *Ammophila* on fixed dunes at Baltrum island, northern Germany, North Sea shore (J.Loidi).

eventually causes the dying-off of the scrubs, and depending on the soil development, higher, spiny shrublands (subtype 1), or grasslands replace the Sea-buckthorn shrubs. In many dune areas, encroachment with Sea-buckthorn is considered a problem, since the expanding, species poor shrubs threaten to overgrow large areas of species rich dune grasslands. This shrub-encroachment has several causes, amongst them a decrease of natural (geomorphological) dynamics and the decrease of grazing. The serious decline of rabbits in large parts of the dune areas in north-western Europe caused by several subsequent diseases was followed by a large scale increase of dune scrubs with Sea-buckthorn. The most important species in this coastal scrub type are *Hippophae rhamnoides* subsp. *rhamnoides* and *Salix repens* and (mainly subsp. *arenaria*); these species are accompanied by *Ligustrum vulgare*, *Rosa rubiginosa*, *Rosa spinosissima*, and *Sambucus nigra*. Sea-buckthorn shrubs are comprised in the class *Salicetea arenariae* Weber, 1999 (Tüxen, 1952; Géhu and Géhu-Franck, 1983; Weber, 1999; Haveman et al. 2017).

8. Juniper shrubland. A last subtype can be recognized in a broad region encompassing temperate and submediterranean Europe: it is the shrubland dominated by *Juniperus communis*, widespread in old pastoral landscapes and dependent on extensive grazing. These juniper populations distribute in scattered populations forming patchy mosaics with a grassland or heathland matrix. They are distributed on low- to mid-elevation areas from Scandinavia to Italy and from France to the Baltic Countries (Janssen 2016d). Substrates can be base-rich, in which case *Juniperus* populations coexist with the *Festuco-Brometea* communities, or on siliceous acidic bedrock, usually sandy, in which case the accompanying community will be one of the *Calluno-Ulicetea* class. On neutral and calcareous soils the main associate shrubs are *Cornus sanguinea*, *Crataegus monogyna*, *Prunus spinosa*, *Rosa canina* and several *Rubus* species. The high dependence of this shrubland type with the extensive grazing makes its conservation particularly difficult in the modern times; if abandoned and neglected, the succession will lead to woodland (Barkman, 1985; Cooper et al., 2012; Janssen, 2016e; Rejmánek and Rosén, 1988).

Fauna

The already mentioned function of shrubland for fauna is revealed by several animal species which are heavily dependent on this habitat. Forest edges and hedgerows provide shelter and food for many small mammals. Specific shrubland mammals are Garden Dormouse (*Eliomys quercinus*), found in forest edges on good soils, and the related Hazel Dormouse (*Muscardinus avellanarius*), which builds nests in *Rubus* scrub. Many common bird species breed in shrubland, for example Bluethroat (*Luscinia svecica*), Lesser Whitethroat (*Sylvia curruca*), Willow Warbler (*Phylloscopus trochilus*), Hedge Sparrow (*Prunella modularis*), Whitethroat (*Sylvia communis*), Grasshopper Warbler (*Locustella naevia*), Red Backed Shrike (*Lanius collurio*) and Nightingale (*Luscinia megarhynchos*). For amphibians, shrubland is a place to hibernate, but European Tree frog (*Hyla arborea*) and the Stripeless Tree Frog (*Hyla meridionalis*) mainly live in shrubland in the vicinity of ponds and pools. Many insects use forest edges and hedges for migration and foraging. Some of the typical butterfly species are Purple Emperor (*Apatura iris*), White Admiral (*Ladoga camilla*), Southern White Admiral (*Ladoga reducta*), Poplar Admiral (*Limenitis populi*), Camberwell Beauty (*Nymphalis antiopa*), Brown Hairstreak (*Thecla betulae*), Purple Hairstreak (*Quercusia quercus*), Sloe Hairstreak (*Nordmannia acaciae*), Ilex Hairstreak (*Nordmannia ilicis*) and Comma (*Polygonia c-album*).

Natural vs. Anthropogenic Communities. Threats

In a natural ecosystem grazing by herds may result in a patchy landscape in which shrubland occurs in small patches and in and along forests, scattered through the landscape. In Europe such landscapes may have existed thousands of years ago, but for many centuries the landscape patterns are largely the result of human land-use. This is certainly the case for shrublands, which—besides for small stands in waterlogged or extreme dry, rocky or steep conditions—are secondary vegetation types. Hedgerows are the result of long-term human management, and in their form sometimes have a medieval or even older origin. The optimum of this shrubland in western Europe is assumed to have been reached in the 19th century, when large parts of the landscape were heathlands, and forests occupied relatively small areas. In those times the landscape consisted of many small fields owned by different farmers who used shrubs for fencing. With the introduction of modern technology in the exploitation procedures of the farmland, the abundance of thorny hedgerows, particularly of subtypes 1, 3 and 4 described above, has diminished dramatically all over Europe during the 20th century, especially after 1960 in the Atlantic European landscape. This was realized amongst other reasons by removal of hedges. It has been demonstrated that the length of hedge structures declined drastically in several regions during the second half of the 20th century (see for example Petit et al., 2003). This process started earlier though, when barbed wire was introduced for fencing the property limits and many farmers decided to install them replacing the hedges. The advantages were evident, a substantial surface of land was freed to be used as meadow or crop land. This led to a massive replacement of thorny hedgerows by barbed wire fences. Another element in this retreat history has been the concentration of plots belonging to the same owner, in order to get to a much larger average field size for farmland, more suitable for larger machines. This led to the disappearance of many limits between plots, simplifying the reticular web they formed in the landscape and homogenizing it.

With the loss of hedgerows, the habitat for many fauna species disappeared as well, for example the nesting habitat for many farmland birds. Besides the loss of shrubland structures, also a decline in quality occurred, especially in the agricultural landscape. Eutrophication resulted in dominance of a few, robust plant species in the herb-layer, while the use of herbicides and fertilizers lead to a strong decline in insects and other animals. Also more natural stands of shrubland have declined during the last century, partly

due to transformation of semi-natural areas to agricultural land, and partly by the construction of plantations of trees. On the other hand, natural stands of shrubland have increased a lot in the last decades, mainly in continental Europe, due to abandonment of traditional management of grasslands. In fact, in these areas the natural succession towards shrubland and forest is a severe threat to biodiversity. Summarizing, the loss of a big part of the hedgerows has had a negative impact on the function and diversity of the bocage landscape. More recently, in large parts of western Europe the floristic composition of undergrowth of the remaining shrublands changed and impoverished due to hypertrophication. In this process, many characteristic woodland-remnant species are replaced by nitrophillous species, like *Galium aparine* and *Urtica dioica*, and it is reported that even narrow-endemic *Rubus* species fall prey to expanding *Urtica dioica*.

Symmetrical to the retreat of these hedgerows in the farmlands, is its expansion in plots of abandoned land, formerly field or grassland, where it develops rapidly (Fig. 9). This phenomenon is due to the generalized rural abandonment of the peasant population, which release many areas from the land exploitation. In these cases, secondary succession triggers and this thorny shrubland encroaches the area as the previous stage before the forest. A similar story can be told about the juniper shrubland of subtype 8, in which a decreasing tendency is observed in most of the sites where it is present (Janssen, 2016e).

Conservation, Restoration and Sustainable Management

Being a temporal succession-stage in a cultural or semi-natural landscape, shrublands need some type of management for sustainable survival. Ceasing of management leads to succession, in this case the encroachment of trees and higher shrubs, leading towards the development of forest communities. The recovery of the thorny hedges is difficult in the conditions reigning in the current industrial and post-industrial society. This means that some areas should be intentionally preserved from the loss of this vegetation mosaic in regards to the ecosystem services they provide. Restoration can be spontaneous as many of the plants forming these hedges are very dynamic, particularly some *Rubus*, *Crataegus* and *Prunus* species, which are efficiently dispersed by birds and easily germinate in degraded areas facilitating their colonization (Fig. 10). The most common management practices to preserve this vegetation are (extensive) grazing, selective or cyclic cutting of trees, and burning. Also removal of non-native species may be needed in some places. Replanting and even re-establishment of hedgerows is an important restoration practice in some countries, especially in the United Kingdom. An important aspect of restoration is the use of autochthonous plant material for the involved shrubs and trees.

In the case of the hazel dominated shrublands of subtype 2, their cultural forms grazed by sheep or goats suffer from a general abandonment while the primary stands maintain their situation stable.

The broom like shrublands of subtype 6 present the most progressing situation as they are covering large areas that have been abandoned from livestock in Iberia. The occurrence of fires, if not too frequent, favors the maintenance of this vegetation.

These types of shrublands are not included in Annex 1 of the Habitat Directive of the European Union (European Commission, 2013), thus they have not usually been taken into account for any protection policy. In spite of this, the protection and increase of this vegetation types are recommended as they favor ecosystem structural and functional complexity and the soil maintenance.

Abstract

In Western Europe forests are the natural climax vegetation and only about 14% of the total area are grasslands. The largest part of Western European grasslands below the alpine zone are therefore secondary grasslands, originating from human land use. The floristic composition of the region's grasslands was largely shaped by repeated glaciations during the Pleistocene and is today mainly composed of perennial herb species. Grasslands of Western Europe can be placed in 18 phytosociological classes, and joined into nine broadly defined grassland types. These grasslands harbor a rich diversity of different taxa, including many endemic species. Moreover, seminatural grasslands of the region were repeatedly highlighted for their high vascular plant species densities. However, natural and seminatural grasslands are among the most negatively human-impacted terrestrial habitats in Western Europe with a strong long-term declining trend in habitat extent and integrity as well as species diversity and abundance since the industrial and agricultural revolutions but especially from the second half of the 20th century onwards. This resulted in a high proportion of threatened grassland types and species. Major direct drivers negatively affecting grasslands across the region were the large-scale conversion of seminatural grasslands to crops, the expansion of urban and industrial areas, the intensification of seminatural grassland to more productive meadows and pastures as well as the abandonment of traditional land-use regimes. Substantial subsidies for increasing agricultural productivity have greatly worsened such damage. A rethink and the development of appropriate tools to reverse this trend are urgently needed. Recently, various conservation and restoration efforts have been undertaken to maintain, promote and restore grassland extent and diversity.

Delimitation and Physiogeography of the Region

The Western Europe region, as defined here, encompasses nine entire countries (plus the Channel Islands and the Isle of man) as well as temperate parts of France, Italy, Portugal and Spain. The countries included vary greatly in land area, population density and grassland extent. The total land area covered here is 1,607,947 km² (Table 1). The region extends from approximately 41 to 60 degrees northern latitude, from 10 degrees western to 17 degrees eastern longitude and from below sea level in coastal areas of the Netherlands to 4810 m a.s.l. in the Alps.

The climate is mainly temperate to warm temperate with warm summers and without extensive drought, though recent years have seen more climatic extremes and uncertainty. In the Alps, the Pyrenees and low mountain ranges such as the Vosges and the Bavarian forest regions a sub-montane climate can be found (Peel et al., 2007; Klötzli et al., 2010).

Repeated glaciation during the Pleistocene involved the relocation and deposition of glacial and fluvio-glacial sediments and loess. Because of this, Western Europe is dominated by rather young soil types which developed by the dominant soil-forming processes typical for humid temperate climates, namely humus formation, leaching, weathering, clay migration, clay destruction and podsolization on well-drained parent materials, as well as gley and peat formation in poorly-drained areas. The most

Table 1 Included countries of the Western European region and basic statistics on total and grassland area (FAO, 2019) and population size (UN, 2019).

Country	Total area (km ²)	Grassland area (km ²)	Grassland fraction of total area (%)	Grassland fraction of agricultural area (%)	Population (million)	Population density (persons/km ²)
Austria	83,879	13,004	15.5	47.1	8.68	105.3

<i>Western Europe total</i>	<i>1,607,947</i>	<i>227,934</i>	<i>14.2</i>	<i>42.8</i>	<i>294.31</i>	<i>189.8</i>

Values for "Grassland fraction of agricultural area (%)" is the fraction of permanent pastures and meadows of the agricultural area. Area and population values for "France (only temperate part)," "Italy (only temperate part)," "Portugal (only temperate part)" and "Spain (only temperate part)" are estimates, and assuming that grasslands and human population are similarly distributed over the whole country. Values for grassland area are based on FAO MODIS (FAO, 2019) and therefore deviate from Dengler et al. (2020) who used FAO CCI_LC (FAO, 2019).

widespread soil type in Western Europe is therefore Cambisol. However, also leached soils like Albeluvisols and Podzols, ground-water saturated Gleysols, as well as periodically flooded deposit soils like Fluvisols in alluvial or marine areas occur (Jones et al., 2005).

Biogeography, Flora and Fauna

Within the Palaearctic realm, Western Europe comprises the Atlantic and Central European floristic regions (Frey and Lösch, 2004). The biogeography of the region was largely shaped by repeated glaciations during the Pleistocene. These cyclic changes between cold and warm periods favored two completely different plant and animal groups: while populations of species of the first group expanded during warm and retreated during cold periods, the second group acted conversely (Taberlet and Cheddadi, 2002; Varga and Schmitt, 2008). In particular low-growing species which overwinter on or below the soil surface were better adapted to survive these harsh and fluctuating climatic conditions than woody species. Because of this 51% of the 4500 vascular plant species of Central Europe and the Alps are perennial herbs with above-ground buds (chamaephytes, hemicryptophytes), 29.3% are herbs without above-ground parts in winter (geophytes, therophytes) and only a very small proportion are woody (15%) or aquatic species (4.6%) (Leuschner and Ellenberg, 2010). During the cold periods, many organisms survived in Southern European mountain ranges, which provided different topography and microclimates (Bennett et al., 1991; Taberlet and Cheddadi, 2002). In addition, numerous grassland plants expanded after glacier recession from Central Asian and Southeastern European steppes and were able to disperse across Western Europe because of the lack of geographical barriers (Pärtel, 2002; Ewald, 2003) or were intentionally or unintentionally introduced by humans (Leuschner and Ellenberg, 2010).

Origin of the Grasslands

The temperate to warm and humid climate in Western Europe allows forest development. Without humans, different forest types would cover most of the region as potential natural climax vegetation and natural grasslands below the timberline would constitute only about 2% (Bohn et al., 2004). Therefore, the largest part of Western European grasslands below the alpine zone are secondary grasslands, originating from human timber harvesting, forest burning to establish arable fields or grazing of woodlands (Török and Dengler, 2018). Secondary grasslands include both seminatural grasslands and anthropogenic grasslands, the latter also called improved or intensively used grasslands. Azonal and extrazonal grasslands are natural grasslands in areas where forest growth is limited by particular soil or topographic conditions, i.e. salt marshes and dunes, as well as rocky slopes, sandy skeletal soils and naturally disturbed sites (Dengler and Tischew, 2018). In this chapter the focus is on both seminatural secondary and natural azonal and extrazonal grasslands, excluding anthropogenically improved grasslands and wetlands.

Typology of the Communities

Grasslands of Western Europe below can be placed in 18 phytosociological classes (Mucina et al., 2016), and joined into nine broadly defined grassland types (Fig. 1), as defined in the GrassPlot database (Dengler et al., 2018). Table 2 summarizes the relationships of these vegetation types and phytosociological units with the habitat types of the European Red List (Janssen et al., 2016). In the following section, the described grassland types are arranged according to the typology provided by Dengler et al. (2014).

Primary or Natural Grasslands

Alpine grasslands

Grasslands above the timberline in western European mountains are natural zonal grasslands in those areas which are too cold to support forest growth (Fig. 1A). These alpine grasslands are not treated in this chapter.

Azonal and extraazonal grasslands

Natural grasslands occurring locally at small scale within the forest biome on soils that are too wet, too dry, too saline, too shallow and too instable to allow tree growth.

- a. *Rocky grasslands*. Natural grasslands on shallow rocky substrates of the order *Stipo pulcherrimae-Festucetalia pallentis* (class *Festuco-Brometea*) are regularly found at small scale in the both lower mountain ranges of Central Europe as well as in valleys of the Alps (France, Austria, Germany and Switzerland), although they are quite common in Central-eastern and Eastern Europe. In the south-western Alps, Apennines, Cevennes, Pyrenees and Cantabrian mountains, the rocky grasslands belong to the class *Festuco-hystrix-Ononidetalia striatae*. The pioneer vegetation on shallow soils on rocky outcrops is included in the class *Sedo-Scleranthetea*, and is rich in succulents, therophytes and cryptogams (Fig. 1B,C).
- b. *Inland dunes and sandy dry grasslands*. Natural or seminatural dry grasslands on sandy soils are sparsely distributed in Western Europe (Fig. 1D). They are included in the class *Koelerio-Corynephoretea canescentis*, developed mostly as tussock grasslands on inland sand dunes (order *Corynephoretalia canescentis*), although fescue sandy steppes of the order *Festucetalia vaginatae* are also locally present in the Pannonian part of Austria. Also local is the presence of the alliance *Hieracio castellani-Plantaginion radicatae* (class *Festucetalia indigestae*) on south-facing siliceous gravel slopes of the Cantabrian range in Spain.
- c. *Saline communities*. Grass- and herb-dominated communities in coastal areas of Western Europe belong to the class *Juncetea maritimi* (Fig. 1E). Intermixed with these natural perennial grasslands and rushes, we can find pioneer vegetation of annual succulent halophytes included in the class *Thero-Salicornietea*. These pioneer succulents are also occurring in inland salt marshes, which are quite scarce in Western Europe. Even more local in Western Europe are the natural continental inland salt steppes (class *Festuco-Puccinellietea*), which are only present in a small area of Austrian Pannonia.
- d. *Coastal dunes*. Atlantic coastal dunes of Western Europe are colonized by vegetation types of the classes *Ammophiletea*, which includes tall-grass perennial swards on mobile dunes (Fig. 1F), and *Helichryso-Crucianelletea maritimae* on stabilized gray dunes. Traditional land use in this system, especially of gray dunes in the Netherlands and Germany and machairs of Ireland and the Scottish isles, is extensive grazing.

Secondary Grasslands

Xeric grasslands

These dry grasslands occur in the xeric zone of the hydrological gradient, and can occur both as secondary and natural grasslands. They belong to the class *Festuco-Brometea*. In west and south-west Europe, these grasslands are mostly placed to the orders *Artemisio albae-Brometalia erecti* and *Brachypodietalia phoenicoidis*. The order *Festucetalia valesiacae*, which is zonal in the steppe and forest-steppe zone of Europe, occurs extraazonally in Austria, eastern France, Germany, Italy and Switzerland. It is mainly restricted to south-facing slopes in xerothermic mountain valleys (Fig. 1G). Only in the Pannonian area of northeast Austria they might be considered zonal grasslands. In north-eastern Italy the dry steppe grasslands of the order *Scorzonetalia villosae*, which are widespread in SE Europe, extend to their north-western distribution border.

Meso-xeric grasslands

Dry grasslands growing on meso-xeric soils. Most meso-xeric calcareous grasslands of Western Europe belong to the order *Brachypodietalia pinnati*, in the broad class *Festuco-Brometea*. These seminatural grasslands are maintained by extensive grazing, but also by mowing or sometimes burning (Fig. 1H).

Mesic grasslands

Meadows and pastures on humid but well-drained soils. The most widespread is the class *Molinio-Arrhenatheretea*, which includes seminatural grasslands on nutrient-rich soils maintained by mowing and/or grazing. Two orders correspond to mesic grasslands: *Arrhenatheretalia elatioris*, on low- to mid-elevations (Fig. 1I), and *Poo alpinae-Trisetetalia*, on mountain ranges. This vegetation type also includes most secondary mat-grass swards included in the class *Nardetea strictae*, typically on nutrient-poor soils, and optimally developed in temperate Atlantic areas and the Alps. Finally, also included in this group of mesic grasslands are the upper

montane and subalpine occurrences of the high mountain classes *Juncetea trifidi* on acidic soils and *Elyno-Seslerietea* on calcareous soils, which comprise natural grasslands in the alpine zone.

Wet grasslands

Temporarily wet and floodplain meadows. Wet meadows and rushes of the order *Molinietalia caeruleae* (class *Molinio-Arrhenatheretea*) are frequent in Western Europe (Fig. 1J), but this grassland type also includes hygrophilous oligotrophic meadows on peaty soils of the alliance *Nardo-juncion squarrosi* (class *Nardetea strictae*). Submediterranean amphiadriatic wet meadows of the order *Trifolio-Hordeetalia*, are widespread in the Balkans, but also occur in the Apennines, while Mediterranean humid grasslands of *Holoschoenetalia* are present in the submediterranean areas of Spain and France. These mainly seminatural grasslands are maintained by grazing or mowing.

Ecology and Biodiversity Patterns

Grasslands cover about 14% of Western Europe (Table 1). Natural grasslands below the timberline would constitute less than 2% of the potential natural vegetation (Bohn et al., 2004). However, grasslands are very important for the biodiversity of many taxonomic groups, such as butterflies (WallisDeVries and van Swaay, 2009), spiders (Polchaninova et al., 2018), grasshoppers (Detzel, 1998), reptiles (Laufer et al., 2007), birds (Nagy, 2009), vascular plants, bryophytes and lichens (Visconti et al., 2018).

European grasslands harbor 18.1% of the 6200 European vascular plant endemics and particularly Western European grasslands host a relatively high proportion of range-restricted species, with a higher proportion of basiphytic endemics (Hobohm and Bruchmann, 2009). According to Grime (1973), European grassland communities on acidic soils are generally characterized by lower species numbers than those on calcareous soils. Ewald (2003) explains this by the theory that in Southwest Asia and Southeast Europe extensive steppe areas existed on calcareous soils. In the course of the species formation process during evolution, numerous plant species have adapted to these conditions. These species were able to spread according to Pärtel (2002) and migrate to Europe via the “renewed” areas with calcareous soils during the Pleistocene. For this reason, according to Ewald (2003), basiphytes now account for a much larger share of the total species inventory in Europe than acidophytes.

Seminatural grasslands of Europe have been highlighted as global record holders in small-scale vascular plant diversity for areas larger than 100 m² (Wilson et al., 2012). In Western Europe, the maximum richness values are not far from the global records, and for the 10 cm² size, the global record is located in Western Europe, specifically in Navarre (Spain), in a Pyrenean valley, with 19 vascular plant species (Table 3). Particularly meso-xeric grasslands are the richest in vascular plants for all area sizes regarding both maximum values and mean values (data extracted from the GrassPlot database; Dengler et al., 2018).

Similar patterns can be observed for bryophytes, with maximum richness values in meso-xeric grasslands, although mean values are distributed among several grassland types: the highest means are once again for meso-xeric grasslands, except for the sizes 10 m², where wet grasslands have the highest values (6.6 ± 4.0), and for 0.1 m² in rocky grasslands with a mean of $2.9 (\pm 2.9)$. Diversity patterns change completely when considering lichens: the highest species densities occur in sandy dry grasslands except for 100 m², where a meso-xeric grassland from Brandenburg (Germany) holds the Western European record, with 31 species. Boch et al. (2016a) reported an outstanding value of 36 lichen species on 16 m² in a calcareous grassland in Germany (Baden-Württemberg; see dataset Boch et al., 2016b). As regards mean values, sandy grasslands are also the richest, except for the 1 and 100 m² large areas, where the richest are rocky grasslands.

Threats

Grasslands of Western Europe are among the most negatively human-impacted terrestrial habitats, which has led to a strong long-term declining trend in habitat extend and intactness as well as species diversity and abundance since the second half of the 20th century (Visconti et al., 2018). Habitat destruction and degradation by the conversion of grasslands to built-up areas and arable

Table 3 Western European maxima of vascular plant species richness per area (shoot presence; Dengler et al., 2018).

Area (m ²)	Max. species number Western Europe	Vegetation type	Location	Max. species number Europe	Max. species number global

fields (e.g. to grow crops for biogas production), as well as land-use intensification and abandonment were considered being the major past and current drivers of grassland threat in Western Europe (Visconti et al., 2018; Dengler et al., 2020). Apart from those which occur in very dry situations, seminatural grasslands depend not only on particular combinations of climate and soil but also on repeated defoliation through herbivory by stock and wild animals and/or by mowing for crops of herbage. Any process which frustrates such relationships poses a threat and two main dangers impact strongly and widely on European grasslands at this time (Janssen et al., 2016; Dengler and Tischew, 2018; Török and Dengler, 2018). First, especially with more mesic and certain wet grasslands, the need for increased agricultural productivity has seen a shift from manuring with dung to the liberal use of chemical fertilizers or concentrated liquid animal manure in slurry (Fig. 2). This has enabled more intensive stocking of pastures for meat and milk production (Fig. 3) and the change from traditional meadow management to cutting of silage rather than hay for forage or indoor feed (Török et al., 2016). Such change began early in the more industrial parts of Europe but has been much encouraged in recent

decades by financial incentives, more universally available through the EU Common Agricultural Policy. These “improved” grasslands now provide the mainstay of European pastoral agriculture (Fig. 4).

The eutrophication of soils has often been accentuated by atmospheric nitrogen deposition and ground-water enrichment from farming itself and from industrial and domestic effluents, especially in the lowlands of more populous regions (Stevens et al., 2010). With land-use intensification, these changes have resulted in a dramatic loss of overall grassland biodiversity (Allan et al., 2014; Visconti et al., 2018), among vascular plants themselves (Socher et al., 2012), bryophytes (Boch et al., 2018a,b), lichens (Boch et al., 2016a), but also in soil microbial populations (Bardgett et al., 1999) and associated invertebrate and bird fauna (Heim et al., 2015). In addition, the land-use intensification strongly affects associations among taxa (Manning et al., 2015), changes species composition and community stability with a loss of specialist species, leading to homogenization of communities (Blüthgen et al., 2016; Gossner et al., 2016). This further negatively affects ecosystem multifunctionality (Soliveres et al., 2016a,b). The great variety of highly distinctive grasslands adapted to particular local soil and climate conditions and long histories of traditional management has converged into a few impoverished types of intensive pastures and leys. Such changes have often been accompanied by a disintegration of cultural features and practices associated with traditional farming: e.g. change of use in traditional buildings, loss of memory of landscape names, abandonment of seasonal festivals (Rodwell, 2015).

A second major threat has come from abandonment of grassland management, sometimes with a shift into arable cultivation, but more widely because of a reduction or withdrawal of grazing or mowing of naturally less productive grasslands (Visconti et al., 2018). Such changes in pasturing or abandonment of mowing have often been a consequence of wider demographic, socio-economic and cultural shifts leading to the extensive spread of heath, scrub and woodland (e.g. Valkó et al., 2018; Boch et al., 2019a,b). More recently, programs of “rewilding” and tree-planting for biofuels or carbon capture have exacerbated this second major threat across Europe.

Of more localized impact, but especially important for wetter seminatural grasslands dependent on regular regimes of seasonal flooding or ground-water supply, have been changes in hydrographic regimes because of water abstraction or in flood-control schemes within river basins (García-Baquero et al., 2016). In other situations, draining of species-poor wet grasslands can diversify plant species composition, provided there is not too intense eutrophication by fertilizers.

Grasslands on stable coastal dune sands have also suffered from lowering of the water table through water abstraction but more widespread losses have occurred through urbanization and the spread of tourist infrastructure. Upper salt-marsh grasslands have been reduced by industrialization on coasts and in estuaries (Janssen et al., 2016).

Invasion of nonnative plant species tends to be limited in the closed swards of grasslands where management has been stable (Visconti et al., 2018) but in lowland meadows of the northern Iberian Peninsula, the South American dallis grass (*Paspalum dilatatum*) has established very widely (Campos et al., 2013). In addition, also in sand dunes and heathlands the rapid colonization of the invasive moss *Campylopus introflexus* suppresses other species such as vascular plants, bryophytes and lichens in 21 European countries (Essl and Lambdon, 2009; Essl et al., 2013).

Impacts of climate change on these grasslands are at present limited (van Oijen et al., 2018) but disruptions in the regular patterns of temperature and rainfall (e.g. longer growing seasons, more frequent drought, irregular flooding) might be expected to affect plant species composition and productivity of grasslands and associated populations of pollinating insects, either directly or through shifts in styles of farming.

Conservation, Restoration and Sustainable Management

The European Red List of Habitats assessed that over 50% of seminatural grasslands were threatened in some way, with many in Western Europe in the Endangered or Vulnerable categories (Table 2). Many such grasslands figure as Priority Habitats in the EU Habitats Directive, are regarded as in urgent need of conservation by many country statutory agencies and often figure in campaigns of wildlife NGOs. However, most farm subsidies continue to favor high-productivity grasslands and biodiversity benefits can be offset against intensive farming.

In addition to overall loss of biodiversity and extent, many surviving grasslands now remain as fragments within highly intensive landscapes presenting additional problems of maintenance and restoration. Even when these remnants are well conserved, connectivity within a wider landscape presents challenges for plant and animal populations and for scenic value. The importance of larger-scale tracts of grasslands has been recognized in the concept of High Nature Value Landscapes (Akeroyd et al., 2014).

The conservation of seminatural pastures and meadows demands a maintenance or reinstatement of existing methods of management or some replacement treatments that mimic such regimes. Traditional management was often an integral part of farming cultures that are now uneconomic, with skills like stock rearing and hay-making becoming lost and traditions such as the naming of fields and community celebrations of harvest losing their meaning.

With huge and continuing loss of seminatural grasslands and continuing threats, restoration is now widely undertaken using a variety of methods (Mora and Bueno, 2018; Warwickshire County Council, 2018). Crucial to all of these is the availability of sites with generally low fertility (particularly of phosphates); some source of suitable herbage or seed; appropriate aftercare; long-term commitment of participants; and effective monitoring. Where, as often, fertility of donor sites is high, some technique of nutrient-stripping is essential, either by top-soil removal or soil inversion using deep plowing or, generally slower, by hard-grazing and repeated cutting of herbage (Kiehl and Pfadenhauer, 2007; Török et al., 2011).

On sites with lower fertility, species-enrichment of existing swards can be undertaken. A variety of restoration approaches has been tried. Translocation is the moving of vegetation and soils, preferably as intact turfs, from a donor to a receptor site where habitat conditions are as similar as possible. It is usually regarded as a last resort when it is impossible to protect a threatened site and, even when more successful, cannot avoid disrupting ecological processes and the historical landscape continuity of the original grassland. Current best practice (Box and Stanhope, 2010) recommends that cutting should use lightweight equipment, transfer should be quick, turfs laid tightly and in the same arrangement as when cut, then rolled and watered.

Where intensive farming of pastures and meadows has not been too damaging, elements of a seminatural seedbank may remain within the soil and be able to contribute to establishment of a more diverse flora (Klaus et al., 2018a,b). Natural colonization of prepared sites by seed is usually slow but may be successful if new locations are adjacent to established grasslands and there is some means of spreading of seed by stock or machinery movement. Sowing seed mixtures, with appropriate composition mimicking that of the target grassland type and of local provenance, has sometimes proved successful particularly where the sward is disturbed and opened up (Klaus et al., 2017; Schäfer et al., 2019). Strewing green hay cut from established meadows is also now widely used and often effective in enriching existing grasslands.

In the early stages of restoration, stress-tolerating specialists, often the distinctive species of the target grassland, perform rather poorly while more competitive generalists can quickly gain an advantage, further limiting specialists or new recruitment from seed by the occlusion of microsites. The presence of an appropriate microbial flora may also prove crucial (Walker et al., 2004).

In all restoration programs, there needs to be a commitment to long-term management and adequate monitoring of benefits. Even in meadows where mowing is an essential part of aftercare, grazing before and after cutting a hay crop has been shown to be essential for effective restoration. Most studies from seven European countries have shown that positive results took more than 10 years to appear (Conservation Evidence, 2019).

Abstract

This chapter deals with the grasslands of Northern Europe (Denmark, Faroe Islands, Finland, Iceland, Norway, Sweden) and the Baltic States (Estonia, Latvia, Lithuania), with a focus on natural and semi-natural grasslands of the lowlands, thus treating arctic-alpine and strongly intensified types only marginally. At present, grasslands cover ca. 7% of the study region, half of which are natural grasslands (mostly arctic-alpine, to a smaller extent also azonal and extra-zonal) and the other half secondary grasslands created by human land use (livestock grazing or haymaking). Both grassland categories have high importance for biodiversity in many taxa. However, particularly the secondary grasslands are profoundly negatively affected by area loss (conversion to other land uses) and quality loss (mainly due to intensification and to abandonment). Conservation measures typically try to mimic traditional low-intensity land uses that are agronomically not profitable anymore.

Delimitation and Environmental Conditions of the Region

We define “Northern Europe and the Baltic States” here based on political territories: Iceland, Faroe Islands, Norway, Sweden, Finland, Denmark, Lithuania, Latvia and Estonia. With the exception of the British Isles which are treated in the Western European grassland chapter of the “Encyclopedia of the World’s Biomes” (Boch et al., 2020), this definition corresponds to “Northern Europe” in the UN Geoscheme. This geographic unit comprises the northern parts of the “Western and Northern European” treatise (Dengler and Tischew, 2018) in the global grassland book (Squires et al., 2018) together with the three Baltic States, which in the book were included in the Eastern European chapter (Török et al., 2018). In this chapter, “Nordic-Baltic region” or “the region” refers to Northern Europe and the Baltic States combined. “Northern Europe” (sometimes also called “Nordic countries”: Denmark, Faroe Islands, Finland, Iceland, Norway, Sweden) and “Baltic States” (Estonia, Latvia, Lithuania) are used to address the two subregions, respectively. Ecologically, the subregions are similar (with differentiation mainly following a North-South gradient), but they differ in land-use history during the 20th century as the Baltic States were part of the communist Soviet Union. In the following, we use “Fennoscandia” to refer to the three countries on the Fennoscandian Peninsula (Norway, Sweden, Finland) but excluding the Russian territory on the peninsula because this is addressed in Tishkov et al. (2020).

The overall territory of the study region is 1.484 million km², extending from 54 to 81° northern latitude and from 25° western to 32° eastern longitude (Table 1). The territory is inhabited by nearly 30 million people but population density varies tremendously from as high as 135 persons/km² in Denmark in the south to only 3.5 persons/km² in Iceland in the north (Table 1). Most parts of the territory are flat to hilly lowland, with the only exception of Iceland, which is a volcanic island with a maximum elevation of 2110 m a.s.l., and the Scandes, covering most of Norway and the westernmost parts of Sweden and reaching an elevation of 2469 m a.s.l.

Table 1 Overview of the region covered in this chapter with its eight political entities, their area and population, grassland area and grassland types.

Region	Denmark ^a	Faroe Islands ^b	Iceland ^b	Norway (including Svalbard and Jan Mayen) ^c	Sweden ^b	Finland ^d	Estonia ^e	Latvia ^f	Lithuania ^g	Total

as fraction of their maximum area (in the past)	10%	95%	95%	NA	NA	NA	NA	33%	NA	ca. 34%
(a) Semi-natural grasslands ^m [km ²]	550	NA	NA	400	NA	400	1150	2150	2050	ca. 22%
(b) Strongly intensified grasslands ⁿ [km ²]	700	NA	NA	6550	NA	2250	1650	6450	6150	ca. 78%

The categorization of grasslands follows the definitions in the "synthesis" chapter by Dengler et al. (2020). The values are rounded expert estimates, only partly supported by hard GIS data. HNV = high nature value; NA = not available.

^aAssessed by H. H. Bruun based on national statistics.

^bTotal grassland area from FAO (2019), based on CCI_LC for the year 2015; subcategories are rough estimates based on ecological knowledge.

^cAssessed by H. Sickel based on national statistics.

^dAssessed by T. Birge based on national statistics.

^eBased on data from Török et al. (2018).

^fSemi-improved grasslands (included here in semi-natural grasslands s. l.) make up 15%–20% of all secondary grasslands, in addition to 7.9% semi-natural ones in the stricter sense. Moreover, 1740 km² of temporal grasslands were counted under grasslands following the definition of Dengler et al. (2020), while in other land use classifications they might be included in arable lands.

^gAssessed by V. Rašomavičius based on national statistics.

^hHNV grasslands = natural grasslands in good state + semi-natural secondary grasslands.

ⁱSteppes = climatogenic grasslands in regions where the climate is too dry to sustain forests.

^jArctic-alpine grasslands = climatogenic grasslands in regions where the climate is too cold to sustain forests.

^kAzonal + extrazonal grasslands = pedogenic grasslands in forest climates, e.g. coastal dunes, salt marshes or grasslands of rocky outcrops, such as alvars.

^lIn good state vs. strongly degraded is roughly separated at a biodiversity loss of 50% (Dengler et al., 2020).

^mSemi-natural grasslands are those secondary grasslands that still contain at least 50% of the original biodiversity (Dengler et al., 2020), which is less strict than other definitions. Accordingly, also semi-improved grasslands as well as some grasslands that recovered or were restored from former arable fields and early successional stages of abandoned grasslands belong here.

ⁿStrongly intensified grasslands are those secondary grasslands that host less than 50% of the typical biodiversity of "good" semi-natural grasslands (Dengler et al., 2020). Accordingly, also most temporary and frequently re-seeded grasslands belong here.

The climate of the region is very mild for its latitude due to the Gulf Stream and the North Atlantic Drift, as well as due to dominating southwesterly winds. The climate is humid as there is cyclonic rain in all the seasons, with a maximum in late summer and autumn (Dahl, 1998). According to the Köppen climate classification, most parts of Scandinavia experience a cold climate with cold summers and no drought (Dfc type and, in the far north, tundra climate ET type). However, most of Denmark, the southern parts of Finland and Sweden, and the Baltic States have cold climate with warm summers and no drought (Dfb type). Additionally, Southern Denmark lies in the temperate climate zone with warm summers (Cfb) (Peel et al., 2007).

During the last (Weichselian) glaciation, the vast majority of the territory was covered by the Eurasian ice sheet complex and the separate Icelandic and Faroese ice sheets, with the exception of southwestern Denmark and tiny areas in southern Lithuania (Patton et al., 2017). From the last glacial maximum at 23 ka BP, the ice shield retreated to reach the current status with only a few remaining mountain glaciers approx. 8.7 ka BP (Patton et al., 2017). However, the post-glacial rebound is still affecting the region today (Patton et al., 2017) particularly the Bay of Bothnia, where post-glacial land uplift at a maximum rate of more than 5 mm relative to sea level creates new terrestrial surfaces. Glaciation has influenced geomorphology of the region significantly and has created considerable diversity in the landscape.

Grasslands have developed on a variety of soils from calcite-bearing parent soils to acidic soils developed from sandstone, gneiss or granite. Mesic grasslands occur on deep soils formed on quaternary deposits. Fertile types of mesic meadows and pastures occur mostly on Luvisols, while poor pastures rather inhabit Planosols or Podzols, the latter being the most widespread soil type in Fennoscandia. Semi-dry and rocky grasslands most commonly develop on shallow calcareous soils (Leptosols) which reach their greatest coverage in the Baltic Sea islands, southern Sweden, and western Estonia. Arenosols support dry sandy grasslands and mesic nutrient-poor *Nardus* grasslands across the region but they are the most widespread in Sweden and in parts of Latvia, Lithuania, and Denmark. Floodplain grasslands grow mostly on Fluvisols, which are common in Baltic States but less frequent in Fennoscandia. Moist and wet grasslands are commonly found on Gleysols, Estonia being the richest in such areas, and Histosols (Reimann et al., 2003; Jones et al., 2005; Tóth et al., 2008).

Biogeography, Flora and Fauna

Due to the humid climate, forests form the zonal vegetation in most of Northern Europe and the Baltic States. Regions with short periods of frost (Denmark, southernmost tip of Norway and Sweden) belong to the nemoral zonobiome (ZB VI), which are naturally dominated by broad-leaved forests (Walter and Breckle, 1986). Regions further north with longer winters and cooler summers (most of Sweden and Finland) are classified as boreal zonobiome (ZB VIII) and naturally covered by coniferous forests (Walter and Breckle, 1986). Between both zonobiomes, a transition zone, the so-called boreonemoral zone (zonoecotone VI–VIII) occurs where broad-leaved and coniferous trees jointly form the tree layer (Baltic States, south Finland, south Sweden, non-alpine parts of Norway). In the northernmost tip of Fennoscandia, the Scandes and Iceland, the tundra biome prevails (ZB IX sensu Walter and Breckle, 1986).

The study region comprises four floristic provinces (Finnie et al., 2007). The Northern European province coincides with the boreal zonobiome. The border of Central European and Eastern European province runs through the territory of Baltic States. The western parts of Denmark and the most southwestern tip of Norway belong to Atlantic European province. Phytogeographers of the Baltic States argue for the delimitation of a separate Baltic province. The southwestern boundary of the Baltic province coincides with the boundary of the boreonemoral zone. The northern boundary of the continuous *Carpinus betulus* distribution range is the outline of the transition of the Baltic province into the Central European province. The distributional boundary of several continental species, such as *Koeleria glauca*, *Astragalus arenarius*, *Pulsatilla pratensis*, *P. patens* and *Silene chlorantha*, marks the southeastern boundary with the Eastern European province (Eilart, 1975).

The flora and fauna of the region is “under-saturated” with species because of the recent glaciations, which “reset” the biota. Immigration of species after the retreat of glacial sheet is still ongoing, and the limited duration of the postglacial period has provided limited opportunity for in-situ speciation (Dahl, 1998). The floristic elements of northern Europe tend to be composed of wide-ranging species and include only a low proportion of European endemics (Finnie et al., 2007). The endemics of the region are mostly infraspecific taxa in apomictic polymorphous groups or allopolyploids, with only a few being accepted at the rank of species (Dahl, 1998; Jonsell and Karlsson, 2004). Grasslands comprise several such endemics, especially on the islands of the Baltic Sea. They are, for instance, *Helianthemum oelandicum* subsp. *oelandicum*, *Galium oelandicum*, *Festuca oelandica*, *Crepis tectorum* subsp. *pumila*, and *Allium schoenoprasum* var. *alvarensense* (Dengler et al., 2006). A second “hotspot” of endemism are the Baltic shores, mostly with grassland taxa (Jonsell and Karlsson, 2004). In Finland, seashore meadows are a habitat type for which the country has an international responsibility. The seashore meadows are important for endemic species, and Finland’s international responsibility stems from the uniqueness of the post-glacial land uplift quality of the seashore meadows (Lehtomaa et al., 2018).

The biota outside the glacial limits were also affected by cold and arid climate during the Pleistocene. Nevertheless, the lack of glaciation in southwestern Denmark and southern Lithuania (Patton et al., 2017) resulted in comparatively high species richness there (Lawesson and Skov, 2002). Similarly, the dune heath of the Atlantic province is a special responsibility for Denmark, harboring a few endemic species, such as *Euphrasia dunensis* (see Jonsell and Karlsson, 2004) and the grasshopper *Corthippus jutlandica*.

Origin of the Grasslands

In the region, natural arctic-alpine grasslands are widespread in the tundra biome. Azonal and extraazonal natural grasslands, including steppe-like semi-dry grasslands, heathlands, and coastal grasslands on saline to brackish wet soils, occur throughout the region in areas where edaphic factors or natural disturbance hamper tree growth. However, grazing by large herbivores or surrogates thereof, nowadays livestock grazing and mowing, is essential for long-term stability of such grasslands. Semi-dry grasslands with floristic elements of steppe are especially abundant on the islands of Öland (Fig. 1E), Gotland and Saaremaa in the Baltic Sea. These islands are arguably the best candidates in the region for a zonoecotone between the nemoral and the arid-temperate continental zonobiome (ZB VII; Walter and Breckle, 1986). Secondary grasslands, both semi-natural and intensified types, prevail in the two forest biomes and their zonoecotone. They have been created by clearing of forests and need regular mowing, livestock grazing or burning for their maintenance.

The origin of temperate grasslands in the Nordic-Baltic region is disputed. There are two main lines of reasoning. Habitats for the grassland biota may be naturally present in sufficient area coverage in mosaic with dominant forest and woodland (Svenning, 2002), or—alternatively—grasslands of the region owe their existence entirely to human pastoralism and shifting agriculture from the Neolithic and onwards (Iversen, 1973; Pott, 1995). There is no doubt that human land use has radically expanded grassland habitats through the last few millennia, hence the term “semi-natural grassland” (Marquer et al., 2014). Likewise, there is little doubt that entirely open landscapes devoid of trees are cultural products. However, different lines of evidence suggest a long-term existence of habitat for grassland biotas in the region. Evidence from the Eem interglacial and earlier is very scarce, due to the resetting effects of the later Weichselian glaciation, almost entirely covering the region at its maximum (Patton et al., 2017). However, pollen assemblages in Eemian palaeosols from western Jutland have been found to contain a certain grassland element (Andersen, 1965; Björck et al., 2000). It is thought that large herbivores—interacting with local climate and soil conditions—have influenced vegetation structure to allow a significant grassland element in the biotas (Svenning, 2002; Sandom et al., 2014; Schweiger and Svenning, 2018). The decline of the megafauna was already in an advanced state by the onset of the Holocene (Barnosky et al., 2004). Nonetheless, several palaeoecological studies have found that open vegetation persisted throughout the period in the Nordic-Baltic region (Nielsen et al., 2012; Theuerkauf et al., 2014; Hjelle et al., 2018) and the wider Western Palearctic (Sommer et al., 2011; Holm and Svenning, 2014). However, palaeoecological methods have limited power in discrimination between open forests with a closed field layer (“savanna”) or a mosaic of open grassland patches within dense forests (“forest steppe”).

Just like under current conditions, grasslands or grassland-forest mosaics may have been more likely on certain soil types, such as more drought-prone calcareous and sandy soils (e.g. Theuerkauf et al., 2014), under certain conditions of topography, such as on steep slopes and potentially in places prone to wind-throw or wildfires (Kuosmanen et al., 2018). Furthermore, the isostatic land uplift in the Baltic region has continuously through the Holocene provided new land to become colonized by grassland biotas (Zobel and Kont, 1992; Auffret and Cousins, 2018).

The grassland flora of the Nordic-Baltic region is made up of plant species with an overall distributional center of gravity in Central Europe (Pärtel et al., 2005). Thus, the species of the current flora seem to have survived the Weichselian glacial maximum in Central and Eastern Central Europe and have re-immigrated from there. Recent reviews of landscape openness during the Holocene in Central Europe suggest the continuous presence of grassland habitat throughout the Holocene, as grasslands and open woodlands, and that the Neolithic pastoralism probably first expanded in landscapes that were already somewhat open (Hejman et al., 2013; Kuneš et al., 2015).

Hay meadows came into existence much later. Animal husbandry started in Eastern Baltics only around 2900–2400 BCE (Piličauskas et al., 2018), and the first scythes come from the Iron Age and are dated to the 3rd–4th century in the southeastern part of the Baltic region (Apals et al., 1974), and also Sweden, where the first finds of hay rakes date from the 3rd to 4th century (Pedersen and Widgren, 2011).

Types of Grasslands

Overall, the spatial extent of natural vs. secondary grasslands is similar, with approx. 50,000 km² in each group (Table 1). Natural grasslands are found at large extents on Iceland but cover only rather small areas in the other countries (Table 1; see also Helgadottir et al., 2014). Among the natural grasslands, arctic-alpine types prevail (Figs. 1A and B), while azonal and extraazonal types contribute less than 10% of the total area (Figs. 1C–E) and true steppes (in the sense of climatogenic grasslands in climates that are too dry for forests) are absent from the region (Table 1). Among the secondary grasslands, a majority nowadays are strongly intensified (Fig. 2B), while species-rich, so-called semi-natural grasslands (Figs. 1E–H, 2A, 2C–E) have become a minority (Table 1).

Most of the countries in the region have national classification schemes for their grassland types. Norway, for example, recently adopted a new system called “Nature types in Norway” (NiN; <https://artsdatabanken.no/Pages/135563>), which distinguishes 25 semi-natural grassland types along the three main gradients, soil pH, soil moisture and management (weak–strong). Finland, as another example, distinguishes 12 main types of semi-natural grasslands and grazed woodlands, which are collectively referred to in the country as traditional rural biotopes. These are: heaths, rock meadows, dry meadows, mesic meadows, moist meadows, freshwater meadows, seashore meadows, alluvial meadows, fen meadows, pollard meadows, wooded pastures and grazed woodlands (Kontula and Raunio, 2018). In total, 42 sub-types of traditional rural biotopes were assessed in Finland for the 2018 Red List

Fig. 1 Different grassland types in the Nordic-Baltic region: (A) natural arctic-alpine grassland in Iceland; (B) natural arctic-alpine grassland (habitat type E4.3b in Table 2) in Norway with willow ptarmigan (*Lagopus lagopus*) as a typical bird species; (C) coastal salt marsh (A2.5b) as a natural azonal grassland in Western Estonia; (D) coastal dune grassland (B1.4a) as a natural azonal grassland on Saaremaa, Estonia; (E) alvar vegetation on Southern Öland, Sweden—alvars are calcareous flatrocks with a mixture of natural vegetation on rocky outcrops (E1.1d) in the foreground, semi-natural meso-xeric grasslands on deeper soils (E1.2a) in the background, fens and shrublands; sometimes alvars are considered as extrazonal

of Habitats (Lehtomaa et al., 2018). The Estonian vegetation site type classification includes four main grassland types (dry and fresh, floodplain, coastal, and paludified grasslands) with 14 subtypes (Paal, 1997). In Latvia and Lithuania, grassland classification follows phytosociological approach (Rašomavičius, 1998; Rūsiņa, 2007). In Latvia, 16 habitat types at the alliance level are distinguished (Kabucis, 2001), among which the dry and mesic grasslands include 23 associations (Rūsiņa, 2007).

For the sake of comparability, we provide here an overview of the main grassland types in the region based on the refined EUNIS grassland typology (Table 2), which can now be applied consistently across national borders via an electronic expert system (Schaminée et al., 2016). The same system also underlies the first Red List of Habitats in Europe (Janssen et al., 2016) and clearly connects to the priority habitats of the Habitats Directive of the European Union (European Commission, 2013).

Management and Agricultural Policy

During the period of traditional agriculture, the area of meadows was often greater than that of arable fields within the resource area of each village or isolated farm. The primary management of semi-natural grasslands in Northern Europe was through grazing and hay-making to provide winter fodder. In many cases in traditional agriculture in the Nordic and Baltic countries, animals were turned out to graze meadows only after hay was collected. Pollarding was once a common form of fodder collection in the Nordic countries and produced distinctive features in e.g. wooded pasture and grazed woodlands. Swiddening was practiced in some areas, leading, for example, to treeless heaths (Berglund et al., 2014). Collection of reeds for winter fodder was also practiced and was instrumental in keeping coastlines open. The grazing and fodder collection under traditional agriculture in Northern Europe created mosaic landscapes and is thought to have had a primarily positive impact on biological diversity at least up until the end of the 19th century (Pykälä, 2001; Berglund et al., 2014). The existing semi-natural grasslands are the most important feature for biodiversity associated with farmlands in the Nordic-Baltic region.

Traditional farming in Scandinavia (lasting until approximately the end of the 19th century) was based on an infield-outfield landscape, where inlands (often fenced) were used as field and hay meadow and outlands (unfenced) were used as pasture (Berglund et al., 2014). In the Baltic States, meadows were located mainly in river flood plains where spring floods ensured natural enrichment of soils. Outside flood-plains, meadows were situated in areas which were not suitable for arable land (e.g. too poor or too wet). The poorest land not suitable even for mowing was used as pasture land. Fallow-lands, fens, forest edges and forests were also grazed (Gustiņa, 2016). Traditionally in Estonia wooded meadows and alluvial meadows were mown, wooded pastures, alvars, and coastal grasslands were used as pastures (Sammul et al., 2000).

Semi-natural grasslands are the result of centuries with domestic animals grazing natural vegetation types and the harvest of wild growing plant material used as fodder for cattle, sheep, horses and goats in the winter months (Emanuelsson, 2009). The animals were normally kept indoors during cold winter months with snow, but were let out to graze as early in the spring as possible. The winter feed was often limited and nutritionally deficient. Thus, it was important to give the animals fresh plant material as soon as possible after the winter. Grazing often took place near the farms in the spring and autumn, but in the summer it was important to save the hay meadows so that they could be harvested for winter fodder. In Finland and the Baltic States, animals were usually allowed on to the hay meadows only after the hay had been harvested. Generally, the animals were herded into forests, heathland, mountain pastures, wetland or other natural vegetation. In Norway and Sweden, it was normal to move the husbandry to summer farms, situated in the subalpine vegetation zone of mountains or in woodland, where grazing resources were almost unlimited. On the summer farms, milk products such as cheese, butter and sour cream were produced, and winter fodder such as grasses, herbs, sedges, lichen, leaves and branches from bushes and trees were harvested (Reinton, 1955). A huge amount of wood was needed as firewood on the summer farms and the landscape surrounding these farms were often open and treeless.

In an effort to make agriculture more efficient, governments replaced the traditional parceling systems for fields and meadows with land ownership based on contiguous property, starting, for example, already in the 18th century in Sweden and Finland. Policy encouraging specialization has played a significant role in the decline of biodiversity-rich semi-natural meadows in the Nordic and Baltic countries, with the loss of mixed farming and decline in small-holdings with a small number of ruminants leading to abandonment, afforestation, or conversion to arable fields. This process happened earlier in the Nordic countries compared to the Baltic countries, and the regions and countries have different histories. Accession to the European Union promoted intensification of grasslands but has also provided countries with financial support for conservation of low-input semi-natural grasslands and wooded meadows.

Once essential to the food production of Northern Europe and the Baltic States, the value of semi-natural grasslands to farm income nowadays is relatively low or non-existent for most farmers. The cost of fodder collection on these sites is viewed by many farmers as too costly for too little return. Hay collection on uneven surfaces is slower, fodder quality is more variable, and fencing more challenging compared to cultivated (intensified) grasslands. Thus, agricultural subsidies are important sources of

income enabling farmers to manage semi-natural grasslands in the region. As a result, cultivated (intensified) grasslands, including grass leys in rotation, now by far exceed managed semi-natural grasslands in the Nordic countries (Helgadottir et al., 2014)—and this process is continuing throughout the region (I. Herzon et al., unpublished material).

Ecology of the Semi-Natural Grasslands of the Region

The activity of grazing and harvesting winter fodder and firewood changed the natural ecosystems and the species composition in them and created semi-natural vegetation types dominated by grasses and forbs. Many grassland plant species have clonal and horizontal growth (e.g. *Knautia* and *Pilosella* species), leaves placed near the ground (e.g. *Primula*, *Pilosella* and *Leontodon* species) or growth nodes located at the lower parts of the plants (e.g. grass species). Even if upper parts of the plants are removed, plants survive and continue growing. Some plants have properties that deter grazing mammals, such as spines (e.g. *Rosa* and *Cirsium* species). Removal of trees and shrubs, mowing and grazing result in increased light conditions and a changed microclimate. Grasslands are therefore also characterized by many small, drought-tolerant and light-demanding plants. Typical plants in grasslands tolerate disturbances and stress, but are rather poor competitors (Grime, 2001). The majority of grassland organisms are adapted to relatively nutrient-poor conditions, under which the competitive strategy is ill-adapted. Also, trampling, grazing and mowing reduce the power of competitive plants. In nutrient-poor grasslands, mycorrhizae are common, in which the fungal partner secures plant nutrient uptake and co-existence (Dostálek et al., 2013).

Grazing and mowing increase the availability of gaps allowing seed germination and establishment. Grazing animals disperse seeds of many plant and animal species - for plants not the least because many grassland plants have seeds tolerating ingestion and gut passage or stick to fur and hoofs. Seeds are also dispersed via transported hay and mowing machines.

Biodiversity: Patterns and Drivers

Semi-natural grasslands are known to be very species rich compared to most other vegetation types in the Nordic-Baltic region (Kull and Zobel, 1991; Austrheim et al., 1999; Eriksson et al., 2002). There are many plants, insects, fungi and birds that live in these open landscapes that are moderately affected by human activity (Artsdatabanken, 2018).

At small spatial scales, Nordic-Baltic grasslands can be very rich in vascular plant species. Among the scale-dependent world records of vascular plant species richness in any habitat reported by Wilson et al. (2012), there are three entries from the study region: 12 species on 0.001 m² in a limestone grassland on Öland, Sweden, as well as 25 and 42 species of a wooded meadow in western Estonia, on 0.01 and 0.04 m², respectively (see Kull and Zobel, 1991). However, for areas of 0.1 m² and larger, mean and maximum richness values of vascular plants in the Nordic-Baltic region more and more lag behind similar grasslands in other regions of the Palaearctic biogeographic realm, such as Eastern Europe, Western Europe, Russia or the Mediterranean Region, the Middle East and the Caucasus (Dengler et al., 2020). For meso-xeric grasslands, the mean richness on 100 m² in the Nordic-Baltic region is “only” about 40 species, while in Eastern Europe, the average is around 75 species (Dengler et al., 2020).

However, one peculiarity of the Nordic-Baltic grasslands is that bryophytes and lichens play a bigger role than in any other Palaearctic region studied (Dengler et al., 2020). This is true across grassland types, but it is particularly pronounced in rocky grasslands where terricolous bryophytes and lichens together on average contribute more species than vascular plants (Ejrnæs and Poulsen, 2001; Boch and Dengler, 2006; Löbel and Dengler, 2008; Dengler et al., 2020). When considering also the bryophytes and lichens growing on other substrata than soil (e.g. saxicolous and epiphytic species), total species richness of the vegetation in rocky outcrop communities of Saaremaa, Estonia, can be as high as 140 species on 100 m² (Dengler and Boch, 2008). However, already when taking only terricolous species into account, the richness of bryophytes and lichens in the rocky grassland communities of the alvars of Öland (Sweden) and Saaremaa (Estonia) are higher for most of the analyzed grain sizes than in any other known Palaearctic grassland type (Dengler et al., 2020).

In a study of a wide range of dry grassland types in Southern Öland, Sweden, Löbel et al. (2006) found that among the studied environmental factors, soil pH was the most important for all three taxonomic groups in the vegetation: it had a positive effect on plot-scale species richness of bryophytes and lichens and a unimodal one on that of vascular plants. Other important factors were microrelief (positive for all taxa, vascular plants and bryophytes) and size of the dry grassland area (positive for all taxa, bryophytes and lichens). Across a wide range of Danish semi-natural grasslands from dry to wet, Moeslund et al. (2013) found that soil moisture (represented by the topographic wetness index) had a strong negative impact on plot-scale vascular plant species richness.

E7.2	Hemiboreal and boreal wooded pasture and meadow	various	6530*	CR

"Code" and "Name in the Red List" are according to Janssen et al. (2016) and Schaminée et al. (2016); the latter also contains distribution maps. "Corresponding vegetation type(s)" refer to phytosociological classes and in four widespread classes of semi-natural grasslands to phytosociological orders (in brackets). Classification is generally based on Mucina et al. (2016), but modified for the class *Koelerio-Coryneporetea* s. l. according to Dengler (2003). Orders (O.) are given only for the four widespread classes of semi-natural grasslands. "Corresponding habitat type(s)" lists the corresponding habitat types that are protected in European Union by the Habitats Directive (European Commission, 2013), with * indicating priority habitats. "RL" finally gives the Red List status at European scale (EU28+; Janssen et al., 2016): CR = Critically Endangered, EN = Endangered, VU = Vulnerable, NT = Near Threatened, LC = Least Concern.

While in the study of Löbel et al. (2006), land use was no influential variable (probably because all the land uses occurring there were of low intensity), many other studies found pronounced effects of land use and land use history. Finnish cattle pastures were most diverse at plot scale when continuously grazed, intermediate when grazing had been restarted 3–8 years ago and lowest in pastures that were abandoned for more than 10 years (Pykälä, 2004). The loss of species in Finnish grassland started almost immediately after abandonment, reached a plateau between year 15 and 40, followed by a second strong decrease afterwards (Pykälä et al., 2005). Swedish calcareous and coastal pastures at the 0.001-m² scale showed a humpbacked relationship to grazing intensity with the moderately grazed plots being richest and the heavily grazed and long abandoned ones being poorest (Dupré and Diekmann, 2001). However, this effect vanished more and more towards larger plot sizes and was absent at 1000 m², meaning that abandoned grasslands did not lose species at larger grain sizes, but just became more patchy, i.e. had higher beta-diversity (Dupré and Diekmann, 2001). One must also consider that there can be a considerable time-lag in the extinction of species when environmental conditions become worse. Helm et al. (2006) demonstrated for alvar grasslands on Saaremaa and Muhu, Estonia, that the negative effects of grassland fragmentation became visible at the plot scale only with decades of delay ("extinction debt").

Semi-natural grasslands are structurally relative simple, but highly biodiverse ecosystems. Co-existence of many different species is governed by many ecological processes, including large mammal grazing, often replaced by extensive human use (e.g. mowing), which interacts with other biotic as well as abiotic factors. Resource limitation is a key factor in maintaining the high diversity and coexistence between plant species in semi-natural grasslands (Pykälä, 2005).

Threats

Among the threat factors of grassland biodiversity, in the Nordic-Baltic region clearly those related to changes in grassland management prevail, in particular abandonment and general intensification, to a lesser extent also overgrazing of un-improved grasslands (Table 3). While natural grasslands lost only a small proportion of their original area to other land uses, secondary grasslands lost about 2/3 compared to their maximum extent, which is the worst situation in all assessed regions of the Palaearctic biogeographic realm (Dengler et al., 2020). However, currently and in the near future further habitat losses due to land use conversions are of subordinate importance. Likewise, altered site conditions, climate change, invasive species and direct impacts of humans and their infrastructure have no or low impact. Only eutrophication is considered of medium importance (Table 3). For the majority of drivers no major change in severity is expected for the next decade, while for abandonment and climate change impacts, we predict an increase in severity (Table 3).

The main threats to grassland ecosystems result from the lack of intact native grazer faunas and the changed agronomic frame around semi-natural grasslands as socio-ecological systems. Grasslands depend on grazing or similar disturbances. However, semi-natural grasslands have a much lower productivity than agriculturally improved grasslands (intensified grasslands in Table 1). Thus, they are the first ones that are either excluded from economic activity of farms by abandonment or intensified to increase their economic value (I. Herzon et al., unpublished material). Accordingly, abandonment and underuse are among the most important drivers of biodiversity and habitat loss during recent decades (Raatikainen et al., 2007; Rüşina, 2017; Lehtomaa et al., 2018; Dengler and Tischew, 2018; Török et al., 2018; see Table 3). Abandonment results from changes in agricultural practices, namely the simplification of farm structure and farming systems. A similarly negative factor is agricultural intensification (Fig. 2B), namely high frequency of cutting, re-seeding, fertilizing and drainage (see Table 3 under “Other forms of intensification” and “Altered water regime”). Generally, intensification affects comparatively fertile grasslands on flat terrain, but abandonment is a bigger threat for dry and wet grasslands, which are located in difficult terrain with harder access for agricultural management. Ultimately, both drivers lead to habitat loss, which in turn results in high fragmentation levels—a threat of grassland maintenance and restoration of its own. The utmost limit of intensification is the conversion of permanent to temporary grasslands, which are reseeded regularly. It results not only in loss of biodiversity but also in decreased chances for restoration of semi-natural grasslands in the future as

Table 3 Overview of the main drivers of grassland biodiversity loss across the Nordic-Baltic region, their current impact (i.e. rate of biodiversity loss caused by them 2010–19) and its anticipated future change (i.e. change in the rate of biodiversity loss in 2020–29 compared to the situation in 2010–19).

<i>Driver</i>	<i>Current impact</i>	<i>Future change</i>
<i>Habitat loss</i>		
Conversion to arable land	Low	± Constant
Afforestation	Medium	± Constant
Mining and energy production	Low	± Constant
Settlements and other infrastructure	Low	± Constant
<i>Changes in grassland management</i>		
Abandonment and underuse	High	Increase
Overgrazing	Medium	± Constant
Other forms of intensification	High	± Constant
<i>Altered site conditions</i>		
Eutrophication (direct and indirect)	Medium	± Constant
Altered water regime	Low	± Constant
<i>Climate change</i>	Low	Increase
<i>Invasive species</i>	Low	± Constant
<i>Direct impact of humans and their infrastructure</i>		
Military and armed conflicts	None	± Constant
Recreation activities	Low	± Constant
Collecting wild plants and hunting	Low	± Constant
Wildlife loss due to electrocution, wind farm collision or traffic	Low	± Constant
Wildfires caused by humans	None	NA

“Current impact” is given on a five-step ordinal scale (none–low–medium–high–very high), while “Future change” was assessed on a three-step ordinal scale (“decrease”–“± constant”–“increase”), where “± constant” means that the biodiversity loss due to this driver is expected to continue in the next decade at the same level as in the previous decade (± 10%). Please note that in order to get an assessment of the expected impact during the next decade, both columns have to be combined: For example, if the current impact is “medium” and the future change is predicted to be an “increase”, the future impact would be “high” (or even “very high”). Likewise, even if the importance of a driver is predicted to decrease, it will in most cases still cause additional biodiversity loss during the next decade. “NA” = not assessed.

restoration in arable land is less successful due to high nutrient levels. A comparison of the Baltic States with three Nordic countries (Norway, Sweden, Finland) showed that the temporary grassland share was as high as 70%–90% in Finland and Sweden, but less than 60% in the Baltic States and Norway (I. Herzon et al., unpublished material). Conversion to arable land and afforestation (Fig. 2H) is also a common threat throughout the region (Table 3). In Norway, habitat loss due to the building of new homes, holiday houses in mountain regions, and roads threatens semi-natural grasslands. Specific threats to wooded pastures and meadows are imbalanced tree stand age structure that causes a lack of trees of certain age brackets, thus reducing the habitat conditions for long-term survival of tree-dependent species (Bergmeier et al., 2010).

Invasive species and climate change are reported as minor threats at present but with potential to increase in the near future (Table 3; see also Dengler and Tischew, 2018; Török et al., 2018). Mostly species-poor grasslands, for instance semi-improved grasslands and grasslands with high disturbance levels, are prone to invasions. The tall forbs *Solidago canadensis* and *S. gigantea* as well as *Impatiens glandulifera*, *Fallopia sachalinensis*, *F. japonica*, in Latvia and Lithuania also *Echinocystis lobata*, *Rumex confertus*, *Bunias orientalis*, and the shrubs *Amelanchier spicata* and *Rosa rugosa* are currently the most widespread neophytes that tend to form dominant stands in former grasslands (Dengler and Tischew, 2018; Gudžinskas et al., 2014). As a result of abandonment and eutrophication, native species such as *Calamagrostis epigejos* and *Pteridium aquilinum* are gaining ground, leading to species-poor mono-dominant stands (Dengler and Tischew, 2018). Other winner species resulting from land-use change are *Anthriscus sylvestris*, *Aegopodium podagraria*, *Arrhenatherum elatius*, *Chaerophyllum aromaticum*, *Galium aparine*, *Urtica dioica*, *Phragmites australis* (in wet grasslands) and *Deschampsia flexuosa* (in dry sandy grasslands) (e.g. Rūsiņa, 2017).

Continuous warming has been documented during spring and summer in the southern parts and during autumn and spring in the northern parts of the Baltic Sea basin (BACC II Author Team, 2015). The duration of the cold season has decreased, duration of precipitation periods has increased and there is an increased risk of extreme precipitation events. For the Baltic States, there has been a significant increase in the number of hot days and nights and the number of heat waves, as well as a significant decrease in the number of frost days. Similar tendencies are projected also in the future (BACC II Author Team, 2015). Widespread increase in atmospheric temperatures and moisture content seems to have rather positive direct effects on vascular plant species richness in grasslands of the region (Dengler and Tischew, 2018). Increased plant species diversity at mountain tops (Kullman, 2010) and alpine insect diversity as a response to glacier retreat (Franzén and Öckinger, 2012) are reported. Still, the high-altitude fauna is expected to be out-competed when temperatures rise (Franzén and Öckinger, 2012). Higher temperatures will promote northward and upward shifts in the boundaries of species occurrence, sometimes at the cost of the original species in that area. For instance, the range of *Lolium perenne*, which is a non-native species in the northern part of the region, will expand. It will change species composition, as it is a competitive species commonly dominating the sward of semi-natural pastures in Central Europe (Höglind et al., 2013). Wet grasslands of the Northern Europe can experience negative impacts due to less ice and snow cover, leading in changing moisture regime during spring. Floodplain grasslands will experience less spring flooding (Apsīte et al., 2013), meaning also less possibilities for dispersal of grassland flora and fauna which is facilitated by floods. It could partly be mitigated by greater water availability as precipitation is forecasted to increase for Northern Europe, thus offering opportunities to restore or create new wet grasslands from intensively managed drained grasslands or croplands (Joyce et al., 2016).

While the negative effects of eutrophication are considered overall as medium (Table 3), there are strong regional differences regarding the atmogenic nitrogen deposition, which for semi-natural grasslands usually is the main source of eutrophication. Denmark is highly affected, Lithuania moderately, Latvia and the southernmost parts of Norway and Sweden at a low level, while this driver is not relevant at all in the majority of the region (Sutton et al., 2011).

Conservation and Restoration

As natural and semi-natural grasslands are highly important for biodiversity conservation in the region, while at the same time many of their types are threatened (Janssen et al., 2016; see Table 2), various grassland types are protected nationally in the countries of the region. Moreover, the European Union, via its Habitats Directive (European Commission, 2013), protects 24 grassland types of the region as of “community importance” (Table 2). Of these, nine are priority habitats, subject to a particular strict protection and monitoring across the countries: “Boreal Baltic coastal meadows” (Habitat type 1630 in Table 2), “Fixed coastal dunes with herbaceous vegetation (grey dunes)” (2130), xeric sand calcareous grasslands (6120), important orchid sites among the “Semi-natural dry grasslands and scrubland facies on calcareous substrates (*Festuco-Brometalia*)” (6210), “Species-rich *Nardus* grasslands, on siliceous substrates in mountain areas (and submountain areas, in Continental Europe)” (6230), “Fennoscandian lowland species-rich dry to mesic grasslands” (6270), “Nordic alvar and precambrian calcareous flatrocks” (6280), “Fennoscandian wooded meadows” (6530) and “Limestone pavements” (8240).

Semi-natural grasslands and wooded meadows are maintained through appropriate grazing and haying pressure. Clearing of scrub is an essential practice for restoration and for management in areas where grazing pressure is insufficient. In the case of seashore meadows, clearing of reeds at the shoreline is frequently necessary for meadow restoration and may be needed periodically even in grazed seashore meadows. Substantial tree felling and clearing of shrubs, such as *Juniperus communis*, is necessary for restoration of afforested and abandoned sites, respectively. As a way of combating abandonment of grasslands, alternative management strategies and uses for biomass beyond fodder have been explored. Since 2010, Estonia has used hay and reed biomass from the extensive semi-natural grasslands of Matsalu National Park to heat the Lihula District, an area of 384 km² (Kask, 2014).

The European Union supports semi-natural grasslands through agri-environment-climate schemes for management and non-productive investment to improve the condition of semi-natural grasslands. Each member country applies these mechanisms, along with own country funds and programs, to support grasslands conservation and restoration according to their agriculture programs

and biodiversity strategies. Additionally, there are specific schemes to support cultivated (intensified) grasslands. Payment amounts, requirements for management and minimum area and type of grassland included in schemes vary across the countries.

The main principles of management for the semi-natural grasslands is no external inputs and sufficient grazing pressure or other management to retain the characteristics that define the habitat type. Development and implementation of site-specific management plans are increasingly being recognized as important parts of sustainable conservation of semi-natural grasslands but are not yet universally practiced. In Finland, for example, site-specific management plans are a requirement for farmers or landowners to receive the agri-environment-climate measure for semi-natural grasslands. Latvia began training farmers in making management plans for their grasslands in 2016. Agri-environment-climate schemes are primarily actions-based, while schemes based on management outcomes, such as those reported from Baden-Württemberg, Germany (Russi et al., 2016), and the Burren, Ireland (Dunford, 2016) are mainly lacking (Herzon et al., 2018), although Finland has a two-tier payment system, with the higher payment reserved for sites deemed nationally or regionally valuable. Countries use obligatory annual management practices and management diaries, along with inspections, as a way to assure that management is carried out. An outcome of support payments being action rather than results-based is that remedial actions such as ploughing to combat invasive species and reseeding are generally proscribed in the schemes.

Land use history affects the biodiversity of sites and their restoration potential, and research supports that grasslands (semi-natural pastures and meadows) have a measurable positive effect on biodiversity compared to other farmland land-use types (Santangi et al., 2019). The most valuable semi-natural grasslands have been under continuous management for hundreds of years, but these are increasingly rare. Commitment to management and restoration varies across the Nordic-Baltic region. Estonia has implemented a large-scale restoration of its seashore meadows and alvars and revitalized associated grazing in recent years (<https://life.envir.ee/english-project-life-alvars>; Kasari et al., 2018). The primary concern for semi-natural grasslands in Latvia is finding ways to make the low-input hay-making and pasturing viable for farmers. Finland recognizes the dire state of its semi-natural grasslands and grazed forests, collectively known as traditional rural biotopes, as the country's most threatened habitat type but has been unsuccessful in increasing the overall area under management (Lehtomaa et al., 2018). In Norway, semi-natural mown grasslands (hay meadows) are critically threatened (CR, Artsdatabanken, 2018), and are a "selected habitat type" according to the Norwegian Act on Natural Diversity. Since 2009, Norway has run an Action Plan for Hay Meadows (Direktoratet for naturforvaltning, 2009), through which it has organized management of approximately 700 hay meadows. Financial support is provided to landowners and farmers who carry out management of the hay meadows according to a plan made by biologists (Miljødirektoratet, 2016).

Fodder potential of the semi-natural grasslands is largely determined by the northern conditions and the variation in fodder quality and quantity according to habitat type. In the cases of seashore meadows and other lush grasslands, grazing, which should start as soon in the season as possible, is often delayed by the wet spring, which can result in decreased palatability of plants and decreased grazing when the animals are eventually turned out to pasture. Dry summers with extreme drought events will be more pronounced in southern part of the region (BACC II Author Team, 2015), and may also negatively affect fodder quality and regrowth. Along the Baltic Sea coast, occurrence of blue-green algae may result in animals having to be removed from the coastal meadows altogether because the grazing animals cannot drink the contaminated water.

Acknowledgments

We are grateful to Iwona Dembicz (University of Warsaw and Zurich University of Applied Sciences) for providing nice photos from various locations in the study region.

Abstract

Grasslands cover around 282,000 km², corresponding to 14.6% of the total area in the countries of Eastern Europe, here defined as East Europe, Eastern Central-Europe, and the non-Mediterranean part of the Balkan Peninsula. Primary (steppes, alpine grasslands, azonal and extrazonal grasslands) and secondary grasslands (created mostly by forest cuts) provide a wide range of ecosystem services, such as biomass production and food for grazing animals and other herbivores, carbon storage and sequestration, home for pollinators as well as for migratory and breeding birds, water infiltration, purification and storage, erosion prevention and recreation. Both primary and secondary grasslands in Eastern Europe harbor a rich flora and fauna, but they are threatened by area loss, the twin threats of intensification and abandonment, invasive species encroachment, and climate change. Large areas of grasslands in the lowland regions have been converted to croplands, and the remaining grassland fragments are in general degraded by intensified use. Intensified use and application of tillage, drainage, intercropping, high intensity grazing or the use of pesticides, mineral and organic fertilizers have a detrimental effect on flora and fauna. In contrast, low accessible areas in mountains, foothills or other marginal areas, the traditional grassland management is abandoned. To recover or improve grassland biodiversity, in many countries, the re-introduction of traditional management regimes by mowing or grazing have been suggested. In case of completely destroyed grasslands, restoration of grassland vegetation and diversity by spontaneous succession and/or technical reclamation are necessary. While in large-scale restoration programs successes were often reported, it was also noted by the authors that the success of restoration was strongly influenced by the availability of high-quality grasslands in the landscape, acting as donor sites or spontaneous sources of propagules. High quality grassland fragments act as hotspots of biodiversity in landscapes dominated by agriculture; thus, their preservation should be prioritized in conservation actions.

Delimitation and Physiogeography

Grasslands in Eastern Europe cover around 282,000 km², approximately 14.6% of the total area of the countries in Eastern Europe, Eastern Central-Europe and the non-Mediterranean part of the Balkan Peninsula (Fig. 1). With high differences between countries or

Fig. 1 The Eastern European region. The region covers countries of East Europe, Eastern Central-Europe, and the non-Mediterranean part of the Balkan Peninsula. The map was created by Map Chart (<https://mapchart.net/>).

subregions, the proportion of high natural value grasslands can be up to 70% of permanent grassland area (Török and Dengler, 2018; Török et al., 2018).

The Eastern European region is characterized by a cool continental climate with an increasing Mediterranean influence in the south (Peel et al., 2007). The region clearly divides into two main subregions: Central European highlands and mountain chains (the Carpathians, Balkan- and Crimean Mountains) with their intermountain basins (e.g., Great Hungarian Plain) in the South and Southwest and Central and Eastern European Lowlands in the North and Northeast. While the landscape of the southern part of the region is related to the older (Paleozoic or Mesozoic) bedrock or Holocene alluvial deposits, the surface of the lowlands in the north was shaped mostly during the Pleistocene. Young glacial landscapes with lakes are only present in the northernmost part of the region; the vast areas more to the south were glaciated earlier and are covered with older, denudated and transformed tills or glacio-fluvial deposits. Moreover, south of the glaciation borders, a thick loess cover accumulated during the Pleistocene, dominating the landscape and masking older landforms. The region is characterized by the presence of many large rivers (e.g., Vistula, Danube, Dnieper, Dniester, Siverskyi Donets and tributaries), the valleys of which are environmentally rich and harbor valuable grassland sites.

Eastern Europe is the western border of the Eurasian steppe and forest steppe zones, primary steppe grasslands and forest-steppe mosaics historically covered large areas in Bulgaria, Hungary, Moldova and Ukraine (Wesche et al., 2016; Török et al., 2018). A considerable part of the region is situated in the zones of deciduous forests and forest-steppes, where the primary vegetation consists of deciduous and mixed forests or forest-steppe mosaics (Metzger et al., 2005; Erdős et al., 2018a). These areas are dominated mostly by secondary grasslands, created after forest cuts and maintained by regular mowing and/or livestock grazing (Dengler et al., 2014).

Origin and Biodiversity of Grasslands

The grass family appeared almost 90 million years ago, but its diversification and the development of grassland ecosystems happened much later (Gibson, 2009). Grassland ecosystems in South America appeared about 34 million years before present (BP), whereas in Europe the steppe-like grasslands occurred probably 5 million years BP. Natural grasslands have existed continuously since the Pleistocene (2.4 million years BP), and during glacial periods they covered the majority of the European continent in form of steppe-tundra in the north and xerothermic grasslands in the south. It is assumed that present steppes and steppe grasslands in the forest steppe zone (i.e., primary grasslands) originated in the Holocene from the near glacial steppe-tundra (also called “tundra-steppe” or “mammoth steppe”), which dominated the landscape of the region in cold periods of the Pleistocene (Binney et al., 2017; Chytrý et al., 2017). In Ukraine, the steppe range was slightly changing after the last glaciation according to climate fluctuations, being more mesophilous during the relatively warm and humid Holocene Climate Optimum (9000 to 5000 BP; Kremenetski, 1995). Simultaneously, the migration of species from Mediterranean and Asian glacial refugia enriched the steppe species pool during the Holocene, leading to the development of the current European steppe (Korotchenko and Peregrin, 2012). Recent paleoecological research has revealed that, during the climatic optimum, when the large-scale

expansion of dense, deciduous forests occurred in the region, patches of natural grassland ecosystems survived in favorable locations even outside of what is traditionally regarded as steppe and forest-steppe zone (Moskal-del Hoyo et al., 2018; Pokorný et al., 2015). Those isolated refugia, as well as the continuous steppe zone, served as important sources of species for many types of semi-natural grasslands created by humans in the forest zone (Kajtoch et al., 2016).

In the north of the region the biodiversity of the more humid semi-natural grasslands probably originates from both the open forests and from wetlands (mostly fens and floodplains). It is believed that the large ungulates which lived there, including the aurochs and wisent, had a potential to create gaps or maintain openings in the forest resulting from natural disturbances such as windthrows or flooding. Moreover, beaver activity could create treeless areas around watercourses (Hejcman et al., 2013). Noticeably, there is a large number of grassland species with distributions related primarily to the forest zone of Eurasia, indicating the existence of open habitats long before the Neolithic revolution (Pärtel et al., 2005). Such species include *Iris sibirica*, *Gladiolus imbricatus*, *Maculinea teleius*, and *Maculinea alcon*. During interglacial periods their areas decreased because of forests spreading (Pärtel et al., 2007). During the last glaciations in the Holocene, 7500–6800 years BP, neolithic people developed agricultural practices, mainly by introducing grazing, which resulted in the alteration of forests towards semi-natural grasslands (Hejcman et al., 2013).

Palaecological studies validated that some semi-natural grasslands in Eastern Europe already existed between 8500 and 6000 BP (Price, 2000; Barczy et al., 2006), but most of the grasslands of secondary origin were established much later, in the Middle Ages. These secondary grasslands were mostly created by clear-cutting of various types of forests, and reached their largest extent during the last 200 years (Török et al., 2018). For example, it is thought that mesophilous meadows of the *Arrhenatherion elatioris* have developed after medieval times (Poschlod et al., 2009; Hejcman et al., 2013); however, they are among the most widespread meadows today. Pastures are in general older than mown meadows as in most regions the scythe appeared much later than the livestock grazing systems. Also, the age of grasslands is increasing from the North to the South, because regions with drier and warmer climate favoring grassland vegetation are more frequent in the Southern part of the region, while in the North spontaneous shrub and tree encroachment highly suppressed grassland vegetation (Török et al., 2018).

As the steppes and forest-steppes of Eastern Europe constitute the western border of these biomes, many species of the steppe fauna have their distribution limits in the region, like the bobak marmot (*Marmota bobak*), the great jerboa (*Allactaga major*), the thick-tailed three-toed jerboa (*Stylodipus telum*), the gray dwarf hamster (*Cricetulus migratorius*), the steppe lemming (*Lagurus lagurus*), the greater mole-rat (*Spalax microphthalmus*), the northern mole vole (*Ellobius talpinus*), the steppe polecat (*Mustela eversmannii*), the marbled polecat (*Vormela peregusna*), and the steppe ratsnake (*Elaphe dione*) (Akimov and Radchenko, 2009; IUCN, 2019). However, the ranges of some species are limited to Eastern European steppes and semi-natural grasslands, e.g., that of the Podolsk mole-rat (*Spalax zemni*), the sandy mole rat (*S. arenarius*), the Balkan mole-rat (*S. graecus*), and the European ground squirrel (*Spermophilus citellus*; the range of this species extends to Austria). For the speckled ground squirrel (*Spermophilus suslicus*) Eastern Europe together with the European part of Russia constitute the whole distribution range of the species. Especially rich in endemic species, mostly invertebrates, are the steppes of the Crimean Peninsula (Akimov and Radchenko, 2009).

The natural and the semi-natural grassland flora of the lowlands in the region is dominated by species with wide Euro-Siberian distribution. However, there is a group of species, also referred to as Pannonian species, which have most of their range within the described region. They include such important grassland specialists as *Rhinanthus borbasii*, *Festuca vaginata*, *F. wagneri*, *Colchicum arenarium*, *Dianthus diutinus*, *Iris arenaria*, *Pulsatilla pratensis* ssp. *hungarica*, and *Linum hirsutum*. Much more species with limited distributions are related to the mountain ranges in the south of the region, especially those of the Balkan Peninsula, e.g., in Central Serbia and Kosovo (41% of the total number of 490 Balkan endemic plants were recorded in the class Festuco-Brometea (Ácić et al., 2015)).

Like in other parts of Europe, the flora and fauna of semi-natural grasslands contribute much to the overall biodiversity of the region. However, the diversity of these ecosystems is strongly shaped by management regime and human-controlled landscape factors (e.g., a large proportion of grasslands in the surrounding landscape supports the biodiversity of the given grassland area; Janišová et al., 2014). The oligo- to mesotrophic, traditionally managed, semi-natural, temperate grasslands of Eastern and Central Europe hold world-records for vascular plant diversity at small spatial scales (Vassilev et al., 2011; Wilson et al., 2012; Chytrý et al., 2015).

In Romania, 43 species were recorded in a plot of 0.1 m², and 98 within a 10-m² plot (Dengler et al., 2009), while in the White Carpathians, a mountain range on the border between the Czech Republic and Slovakia, there were 67, 88 and 131 vascular plant species in plots of 1, 4 and 49 m², respectively (Merunková et al., 2012). Semi-natural grasslands are important not only for plant biodiversity but also for other organisms. It is, for example, estimated that around 74% of European grasshopper species depend on open habitats (Hochkirch et al., 2016). Semi-natural grasslands seem to be equally important for butterflies (Skórka et al., 2007) and birds (Hoste-Danyłow et al., 2010). Despite recently observed negative trends, eastern European semi-natural grasslands are still hosting higher biodiversity when compared to their western counterparts (Batáry et al., 2010; Żmihorski et al., 2016).

Typology of Grasslands

Grasslands in Eastern Europe can be classified as primary (natural) and secondary (semi-natural) grasslands. Primary grasslands cover sites that are in general unfavorable for the establishment of trees. The most important types are the following:

Steppes and Steppe Grasslands in Forest Steppe Mosaics

Steppes are primary climatogenic grasslands on dry habitats, which are not suitable for the establishment of trees in hilly regions, foothills, and lowlands (Fig. 2A). Steppes are very diverse and mosaic-like habitats characterized by perennial graminoids of *Bromus*, *Elymus*, *Agropyron*, *Festuca*, and *Stipa* species. They are in general rich in forbs, the most frequent genera being *Achillea*, *Artemisia*, *Aster*, *Astragalus*, *Centaurea*, *Inula*, *Linum*, and *Salvia*. There is an early spring aspect characterized by several early flowering species from the genera *Adonis*, *Gagea*, *Ornithogalum*, *Pulsatilla*, and *Tulipa*. Steppe grasslands in Eastern Europe are the westernmost localities of their Eurasian distribution. (Wesche et al., 2016; Török et al., 2016a). In the steppe zone, historically extended steppe grasslands were typical for loess deposits, mostly on chernozemic soils. In the forest-steppe zone, steppe grasslands are components of forest-

grassland complexes (Fig. 2B, Erdős et al., 2014; Erdős et al., 2018a,b). In the region, remaining stands of this grassland type are typical in the Czech Republic, Hungary, Moldova, Poland, Romania, Ukraine, and the countries of the Northern Balkan. Based on recent estimates, the overall extent of this type of grasslands in the region is around 1.1 million hectares (Török and Dengler, 2018).

Alpine Grasslands

Alpine grasslands are climatogenic grasslands occurring in regions that are too cold for the establishment of trees. Based on a recent estimate, there are 500,000 ha of these grasslands in the Eastern European region (Török and Dengler, 2018), but this grassland type is not discussed in detail in this article.

Azonal and Extrazonal Grasslands

Pedogenic or topogenic grasslands, where special habitat properties prevent the establishment of trees. The extent of this grassland type is estimated to be about 400,000 ha in Eastern Europe (Török and Dengler, 2018). There are several subtypes within this grassland type:

Coastal and inland saline grasslands

Pedogenic grasslands in lowland regions, where the astatic water availability and high salt content of the soil prevents the establishment of trees (Fig. 2C and D). These grassland types are the most well-preserved in Eastern Europe, as their soil is unsuitable for agricultural production and can be utilized only with extensive pasture management. The most typical inland saline vegetation occurs in large extents in Hungary and Ukraine, but small fragments are present in all countries with dry lowland regions like Slovakia, Serbia, Bulgaria or Macedonia (Eliáš et al., 2013). These types of grasslands are characterized by a high cover of tussock-forming fescue species (*F. pseudovina*, *F. rupicola*, *F. regeliana*), and several *Puccinellia* and *Juncus* species are also typical, especially in wet places at slightly lower elevations. Characteristic forbs are halophytes or other salt-tolerant species in the genera *Artemisia*, *Aster*, *Limonium*, *Plantago*, *Podospermum*, *Salicornia*, *Salsola*, *Spergularia*, and *Suaeda*.

Sand steppes and coastal sand grasslands

These pedogenic grasslands cover acidic to calcareous sands which are in general unsuitable to sustain trees (Fig. 2E). Their vegetation is characterized by tussock-forming grasses, including fescues (*Festuca vaginata*, *F. pseudovina*, *F. psammophila*, *F. polesica*, *F. beckeri*), *Corynephorus canescens*, *Koeleria glauca*, *Stipa capillata*, and *S. borysthena*. Also, several small clonally spreading *Carex* species are typical (e.g., *C. stenophylla*, *C. praecox*, *C. supina*, and *C. colchica*). Many short-lived forbs are characteristic in the spring, including the genera *Arenaria*, *Cerastium*, *Draba*, *Erophila*, and *Veronica*. Cryptogamic species (mosses and lichens) can reach considerable cover in this type of grasslands. Sand grasslands occurring in the lowlands of the Eastern European region are typical in the countries of Belarus, Croatia, the Czech Republic, Hungary, Poland, Serbia, Slovakia, Slovenia, and Ukraine.

Grasslands on shallow rocky substrates

Because of the steep slopes, high erosion enables only the development of shallow and rocky soils (skeletal soils), which is in general unsuitable for the establishment of trees. This topogenic grassland type typically occurs in small patches near the top of hills and middle mountains (Fig. 2F). The species composition is characterized by xerophytes, and the species composition and richness is strongly influenced by the type of the bedrock (the most species rich grasslands are on limestone or dolomite bedrock; grasslands formed on volcanic or metamorphic bedrock are less species rich). Typical graminoids are *Festuca*, *Bromus*, *Poa*, and *Stipa* species. Frequent forb genera are *Campanula*, *Cerastium*, *Inula*, *Potentilla*, *Spergula*, and *Veronica*. In addition, many species of the Brassicaceae family, as well as several succulent species from the genera *Jovibarba*, *Saxifraga*, *Sedum*, and *Sempervivum* occur in these grasslands.

Secondary grasslands

Secondary grasslands were created by the anthropogenic suppression of phanerophytes and are sustained by regular management—mostly mowing and/or livestock grazing. They can be formed on various substrates from fine alluvial deposits to solid bedrock. Their secondary origin does not necessarily mean that they are less important in biodiversity conservation. In many cases, they are valuable and species rich habitats, sustained by several hundreds of years of extensive management. Secondary grasslands can be classified into the following subtypes:

Dry and Semi-Dry Grasslands

The most valuable meso-xerophytic secondary grassland types, which occur on shallow to deep soils, formed mostly on calcareous or volcanic bedrocks in the whole region, from lowlands to mountains (Fig. 2G). Especially the calcareous types harbor many steppe elements and are extremely species-rich habitats, threatened in many countries by woody encroachment (Eliáš et al., 2018). Dry grasslands are also characterized by high cryptogam diversity. Characteristic graminoids are tussock-forming and rhizomatous species like *Brachypodium pinnatum*, *Elymus hispidus*, *Bromus erectus*, *Danthonia alpina*, *Sieglingia decumbens*, *Avenula pubescens*, *Nardus stricta*, *Festuca ovina*, *Melica altissima*, *M. transylvanica*, *Carex caryophyllea*, and *C. montana*. Characteristic forbs are in the genera

Allium, *Campanula*, *Centaurea*, *Clinopodium*, *Cirsium*, *Geranium*, *Inula*, *Lathyrus*, *Origanum*, *Peucedanum*, *Salvia*, *Thymus*, *Trifolium*, *Verbascum*, and *Vicia*.

Mesic to Wet Grasslands

These types of secondary grasslands are the most common in the region from lowlands to mountain areas. In general they cover medium to deep, in most cases nutrient-rich mesic to wet soils (Fig. 2H). Most characteristic species are generalist graminoids and forbs. Typical tussock forming and rhizomatous graminoids include *Arrhenatherum elatius*, *Alopecurus pratensis*, *Agrostis tenuis*, *Anthoxanthum odoratum*, *Briza media*, *Bromus inermis*, *Cynosurus cristatus*, *Festuca pratensis*, *F. rubra*, *F. arundinacea*, and *Poa pratensis*. Small-growing *Carex* species like *C. pallescens*, *C. panicea*, and *C. tomentosa* are also important. More moist types harbor *A. stolonifera*, *Molinia arundinacea*, *Deschampsia caespitosa*, *Poa trivialis*, further *Carex* species including *C. nigra*, *C. flava*, and *C. flacca*, and *Juncus* species (e.g., *J. conglomeratus*, *J. effusus*). They harbor several forb species from the genera *Achillea*, *Chrysanthemum*, *Dactylorhiza*, *Gentiana*, *Leontodon*, *Lychnis*, *Medicago*, *Mentha*, *Orchis* s.l., *Ranunculus*, *Rhinanthus*, *Stellaria*, *Trifolium*, and *Veronica*.

Ecology and Biodiversity Patterns

As it was mentioned earlier, natural grasslands of the region are usually climatogenic (steppes, steppe grasslands in forest steppe mosaics, and alpine grasslands), pedogenic (sand steppes and coastal sand grasslands), or topogenic (grasslands on shallow rocky substrates). However, besides the crucial role of climate and extreme habitat conditions which prevent woody encroachment, the maintenance of ecosystem functioning, high biodiversity and typical species composition of natural grasslands can also be driven by other factors. For example, in the steppe ecosystem large mammal herbivores and fires are consumers of vegetation, preventing steppe ecosystems from reaching their climatic potential, and thus preventing the accumulation of litter and subsequent changes towards more mesophilous grasslands or shrublands. Many steppe nature reserves face the risk of losing biodiversity due to the implementation of fire prevention measures and the lack of important wild ungulates such as horses and saiga (the latter of which became locally extinct because of hunting and habitat fragmentation) (Havrylenko, 2011).

Microclimatic gradients are important for both natural and semi-natural grasslands. Vegetation typical for more northern zones or more mesophilous sites are occupying northern exposition, while more xerophytic grasslands occupy south-facing slopes (Sudnik-Wójcikowska and Moysiienko, 2008; Sutcliffe et al., 2016). Soil and bedrock gradients are also important in both natural and semi-natural grasslands. The main drivers of species composition are soil pH (e.g., *Nardus* dominated grasslands occur on acidic bedrock), soil depth (e.g., *Festuca pallens* grasslands occur on rock outcrops), and soil texture (sand grasslands on coarse sediments and more steppe-like grasslands on loess). Moisture gradient is important predominantly in semi-natural grasslands, but its role can also be recorded in natural steppes, with depressions being occupied by more mesic vegetation or being prone to salinization. Besides the amount of available moisture, its seasonal variation is also important (e.g., the inundation time or its temporal fluctuations).

However, the most crucial driver of species composition in semi-natural grasslands is the management regime. Mowing promotes graminoids, while grazing usually suppresses them. Furthermore, grazing allows more forb species to develop and replenish (small disturbances and open soil surfaces created by trampling are crucial for the germination of many grassland species). The type of grazing livestock can also be an important factor. Cattle and horses eat the taller grasses while sheep prefer forbs and short grasses (Tóth et al., 2018). Goats, which are browsers, can reduce shrub encroachment into the grassland (Elias et al., 2018). Mowing regime can also influence species composition; for example, early mowing favors early-flowering species. The importance of the fertility gradient should also be emphasized. It is especially important in semi-natural grassland types as natural primary productivity is controlled by moisture deficit. Recent studies point out the role of limiting nutrients in shaping the species composition of grasslands, with different species adapted to N and P limitation (Roeling et al., 2018).

Biodiversity patterns (especially of plants) can be controlled by the same gradients as the species composition of grasslands. In general, the biodiversity of various groups of organisms inhabiting grasslands (especially drier, more xerothermic types of grasslands) is decreasing from south to north in the region, mostly due to the climate and the geological history (glaciation and later the expansion of forests), as well as the mountain ranges forming a barrier for the migration of species from the south (like the Sudety and the Carpathian Mts). However, at regional scales, the patterns can be opposite. For example, in natural steppes in Ukraine plant diversity decreases from the forest-steppe zone to the south, along with the drought stress becoming more intensive. Management type is another important driver of species richness in grasslands, in particular in semi-natural ones. Traditional management usually supports biodiversity, while too intensive management leads to its decline (Cremene et al., 2005). The highest fine-scale richness of vascular plants occurs in semi-natural mown grasslands (Turtureanu et al., 2014), but grazing and small disturbances created by animals can also be important for the diversity of this taxonomic group (Enyedi et al., 2009). It is worth mentioning that the plant richness of natural grasslands, like steppes, is enhanced by grazing and fires (Kuzemko et al., 2016).

Typically, the relationship of pH with fine-scale plant diversity in the region seems to be hump-shaped, with the highest richness occurring under neutral or slightly basic conditions, although under drier conditions the relationship may be negative or non-existent/non-detectable (Palpurina et al., 2017). Well known is the hump-shaped relationship between primary productivity and plant species richness (Fraser et al., 2015). As it was mentioned before, in natural grasslands primary productivity is controlled by

climate (with the resulting pattern of richness in steppe), but in semi-natural grasslands it depends on fertility. Limiting nutrients can influence the richness or the richness-productivity pattern (Palpurina et al., 2019).

The relationship between biodiversity and productivity in grassland ecosystems was much studied (e.g., Grime, 2001; Kelemen et al., 2013; Cerabolini et al., 2016; Sonkoly et al. 2019). The most important factors affecting the productivity of grassland communities are water and nutrient availability, which influence the biodiversity of the community. High values of phosphorus, nitrogen and potassium decrease the biodiversity of grasslands (Merunková and Chytrý, 2012). Bernhardt et al. (2010) reported some data on grassland productivity from different parts of the EU. The regions with the lowest productivity are located in the Mediterranean, with annual yields limited to 1.5 t per ha or even less; slightly higher yields are obtained for mountain areas, which are more mesic, e.g., the Pyrenees and the mountains of the Balkan Peninsula. The Central EU countries (Poland, the Czech Republic and Slovakia) reach fairly high yields, around 4 t per ha, while in the steppe conditions of Hungary, Bulgaria and other southeast European countries, the yields are much lower—about 1.5 t per ha, because of unfavorable water regime and drought.

Ecosystem Services and Threats

Natural and semi-natural grasslands provide a wide range of ecosystem services, such as biomass production and food for grazing animals and herbivores, carbon storage and sequestration, home for pollinators as well as for migratory and breeding birds, resources for flood reduction, water infiltration, purification and storage, erosion prevention and recreation (Peciña et al., 2019). The conversion of grassland into arable land decreases soil carbon because of the reduced carbon input from litter and the loss of carbon by tillage (Jones and Donnelly, 2004). Plant diversity and soil organic carbon pools are thought to be the major factors for the provision of several ecosystem services, mainly pollination, herbs for traditional medicinal use, nutrient cycling, nutrient retention and biomass production (Peciña et al., 2019). In addition to cultural and aesthetic values, grasslands play an important role in nutrient cycling, balancing of the local climate and soil erosion, and sustaining pollinators and biological control agents (e.g., Fantinato et al., 2018). Grassland ecosystems have also attracted substantial scientific and policy interest because of their potential role as sinks or sources for atmospheric carbon dioxide. Conversion of arable land into permanent grassland is one measure that is believed to have a considerable carbon sequestration potential (Ammann et al., 2007). The supply of multiple ecosystem services is decreasing significantly worldwide because of pressures of climate change and other anthropogenic factors, including overgrazing, intensive agricultural production, deforestation, and urbanization (Costanza et al., 2014). Both climate change and grazing exert great influence on the supply and interrelation of ecosystem services (Hao and Yu, 2018). However, modern agricultural practices, mainly referring to intensive agriculture, as well as fragmentation and land-use abandonment in recent decades, have caused a biodiversity loss and consequent conservational concerns, due to negative effects of value and provision of grassland ecosystem services.

Area Loss

The most alarming threat for most of the natural communities including grasslands is area loss. Important causes of area loss are the (i) conversion to croplands and other agricultural areas, (ii) afforestation, establishment of tree plantations and spontaneous forest succession, (iii) and urbanization. The most threatened grasslands are in the lowlands, embedded into intensively managed croplands. Recent estimates suggest that in the last 200 years at least 50% of all grassland area has vanished in the Eastern European region (Török and Dengler, 2018). The area loss is strongly variable between grassland types and/or regions. Bíró et al. (2018) summarized the area loss of 8 natural and semi-natural grassland types in Hungary. They found that the lowest decrease in area occurred in saline grasslands (39%), which are unsuitable for agricultural production, while other grassland types displayed 85–98% decrease in area. A similarly high decrease was reported for the western part of steppes and forest steppes (Deák et al., 2016; Wesche et al., 2016; Erdős et al., 2018b).

One of the consequences of habitat loss is high fragmentation and the isolation of remaining grassland patches, which are exceptionally severe in Eastern European steppes. For example, in the Lugansk region (Ukraine) the formerly continuous steppe vegetation has survived in 2000 fragments that are mostly surrounded by intensive agricultural landscapes (Parnikoza and Vasiluk, 2011). The increasing fragmentation and isolation of semi-natural grasslands is a serious threat for grassland biodiversity in many other countries in the region. Isolation can lead to local extinctions (while immigration from other patches has low probability) and can negatively influence the genetic structure of the populations, as was found in steppe enclaves of southern Ukraine (Dembicz et al., 2016; Wódkiewicz et al., 2016).

Changes in Management: Intensification and Abandonment

Management changes can be considered the most important threats for grassland biodiversity in the Eastern European region. The cessation of former management became typical in the last 50 years in Eastern Europe affecting mostly grasslands in mountainous areas, foothills and other areas with low accessibility (Török and Dengler, 2018). Land abandonment in these regions resulted in the decrease of grassland biodiversity and increased woody encroachment (Valkó et al., 2011, 2012). Land abandonment was especially intensive in the 1960s, when traditional herding management was replaced in many places by the intensive forms of animal husbandry. A second wave of abandonment happened after the fall of the Socialist regimes and the collapse of collective farms.

However, land abandonment also result in a slight increase of grassland areas in lowlands because of the spontaneous recovery of grasslands following cropland abandonment (Ramankutty and Foley, 1999). The access of EU subsidies in countries such as the Czech Republic, Slovakia, Romania and Hungary, impacted grassland biodiversity controversially. In some foothill regions shrub encroachment was suppressed and many grassland sites were cleared from shrubs, which affected grassland biodiversity positively. In other grasslands, subsidies enabled the farmers to improve the management of grasslands and provided a source for intensification, which resulted in the decrease of farmland biodiversity (Sutcliffe et al., 2015). For example, in Romania the subsidies increased the amount of grazing livestock, which, in most cases, meant an increased sheep grazing in high diversity grasslands historically maintained by low-intensity cattle grazing and/or mowing. The process proved detrimental to grassland biodiversity (Roman et al., 2019).

Invasive Species Encroachment

Grasslands were considered in a recent evaluation of invasion threat by Pyšek et al. (2010) as habitats characterized with intermediate levels of invasion and low invasion risk. However, grassland habitats are subjected to highly different levels of invasion and invasion risk. Botta-Dukát (2008) found that there are grassland types that can be characterized by low levels of invasion (e.g., rocky grasslands and saline grasslands), while others like sand grasslands are highly invaded. Plant invasions are strongly associated with the management changes of grasslands. In general, the overuse of grasslands (e.g., overgrazing or improper management) can create many establishment gaps in the vegetation and can facilitate the invasion. Climate change can also interact with this process, e.g., extreme weather events can create bare-soil patches in the vegetation, and increased frequency of droughts and fire favor the establishment of fire-adapted and drought-tolerant C4 grasses (Walther et al., 2009; Török and Aradi, 2017).

Climate Change

An emerging future threat is climate change, which can considerably affect grassland biodiversity in the forthcoming decades. According to the last predictions, (1) the yearly mean temperature will rise by about 1–3 °C, (2) precipitation patterns will be reshaped, as winter precipitation is expected to increase at the expense of summer precipitation, (3) the frequency of extreme weather events (e.g., extreme droughts, wildfires, extreme frosts, heavy rains) will increase in the future (Anders et al., 2014; Wesche et al., 2016). These effects jointly reshape the composition of grasslands by favoring drought-tolerants and ephemeral species, and increasing the proportion of Mediterranean species in the southern and central part of the region (Thuiller et al., 2005).

Some Further Drivers of Grassland Biodiversity

In many countries in Europe, grasslands assigned to the military are well-preserved and sustained because of the limited access and other restrictions in management (Elias et al., 2018). However, recent military conflicts (e.g., in Ukraine) had devastating impact on the subjected regions and embedded grasslands (e.g., uncontrolled fires by explosives, demolition by artillery fires, armored vehicle maneuvers, Vasyliuk et al., 2017). In Western Europe, among the most important threats are nitrogen deposition and aerial eutrophication (Dengler and Tischew, 2018). In the Eastern European region this threat can be considered to be of much lower importance. It was found that the nutrient enrichment of nutrient-limited grassland types (e.g., dry grassland types on shallow soils) can facilitate the increase in the cover of generalist graminoids and, due to their increased biomass production, can also decrease the beneficial effects of management on the grassland biodiversity (Kelemen et al., 2014; Habel et al., 2013).

Conservation, Sustainable Management and Restoration

Conservation

The most valuable grassland habitats can be found in protected areas, most cases in national parks and other nature reserves (e.g., Askania-Nova Biosphere Reserve, Carpathian Biosphere Reserve, Ukrainian Steppe Reserve, Oleshkivski Sands National Nature Park, Slovenský Raj National Park). In general, the active protection of semi-natural grasslands only began in the late 20th century when the approach of nature conservation shifted from absolute non-intervention to active conservation. Until then, the emphasis was mainly placed on species conservation, sometimes not even considering or misunderstanding habitat ecology and the requirements of the species. While due to the non-intervention approach, although there were a very few grasslands in protected nature areas preserved, it made possible to save particularly valuable virgin steppes from plowing (extensive stands were destroyed in the so called “virgin steppe” campaign in the 50s).

One of the main legislative instruments that regulates the protection of grassland ecosystems in Europe, is the Convention on the Conservation of European Wildlife and Natural Habitats (Bern Convention), which principal aims are to ensure conservation of wild plant and animal species and their natural habitats. This Convention provides the basis for development of the Emerald network of areas of special conservation interest. In EU Member States, this type of network is called Natura 2000. Natura 2000 is based on two directives: the Birds Directive and the Habitats Directive. There are more than 4000 Natura 2000 sites, in which there is a noticeable cover of grasslands. Within the Natura 2000 and the Emerald network, management plans are fine-tuned to take into account the environmental requirements of certain habitat types of certain rare or endangered species.

Sustainable Grassland Management and Restoration

In the Eastern European region several grasslands were created and later sustained by extensive forms of management mostly by mowing or grazing (Dengler et al., 2014). Large areas of grasslands in the lowland regions has been converted to croplands, and the remaining grassland fragments are in general degraded by intensified use. Intensified use and application of tillage, drainage, intercropping, high intensity grazing or the use of pesticides, mineral and organic fertilizers have a detrimental effect on flora and fauna (McLaughlin and Minneau, 1995). In contrast, low accessible areas in mountains, foothills or other marginal areas, the traditional grassland management is abandoned (van Dijk et al., 2005). In lowland regions of Eastern Europe, natural and semi-natural grasslands are embedded as small islands in the sea of intensified landscape. These patches also often key elements of High Nature Value (HNV) farmland systems, which are low-input farming systems in terms of biodiversity and management practices. The sustainable management of species-rich grasslands in EU countries of Eastern Europe is made achievable under the Common Agricultural Policy (Oppermann et al., 2012). In Eastern Europe, a high proportion of extensively managed remnants of the traditional rural areas are present (Oppermann et al., 2012). In many countries, the re-introduction of traditional management by mowing or grazing as a restoration tool has been suggested (Török et al. 2016b, Galvánek and Lepš, 2008; Valkó et al., 2011, 2012). Low intensity grazing by herded livestock (local breeds) or free grazing (by wild horses and cattle) are often recommended (Török et al., 2016b,c; Tóth et al., 2018). In many regions the re-introduction of traditional management is not feasible or sustainable; thus, conservation authorities and site managers are seeking substitute management practices (e.g., prescribed burning during the dormant season, Valkó et al. 2014). Instead of a single type of management by mowing or grazing adopting a whole scheme of traditional land use may be required for many grasslands to sustain the extraordinary grassland diversity in a particular region (Babai and Molnár, 2014).

In degraded grasslands, the decrease of management intensity is often recommended, but in case of completely destroyed grasslands (e.g., converted grassland areas), restoration of grassland vegetation and diversity by spontaneous succession and/or technical reclamation are necessary. There were several large-scale grassland restoration programs in Eastern Europe. Most publications were related to grassland restorations in the Czech Republic and lowland regions of Hungary (Halassy et al., 2016; Kövendi-Jakó et al., 2019; Török et al., 2011; Prach et al., 2014; Lengyel et al., 2012). While in large-scale restoration programs successes were often reported, it was also noted by the authors that the success of restoration was strongly influenced by the availability of high-quality grasslands in the landscape, acting as donor sites or spontaneous sources of propagules. These facts underline that the preservation of natural and semi-natural high-quality grassland fragments should be prioritized in conservation actions (Török and Helm, 2017).

Acknowledgments

P.T. was supported by the ‘Momentum Program’ of the Hungarian Academy of Sciences, and by NKFIH (Grants: K 119225 and KH 129483) during manuscript preparation. We are indebted to Judit Sonkoly and László Erdős for kindly checking the manuscript for errors and typos.

Abstract

The Middle East and the Caucasus grasslands and shrublands host a high diversity of habitats, species and land management practices. It is the homeland of the earliest agriculture and many ancient civilizations following it. The land extends across more than 2 million km², spanning the majority of nine countries with 269 million people living within. The variety of climate types, orography and position with respect to four floristic regions (Mediterranean, Euro-Siberian, Irano-Turanian and Saharo-Sindian) play an important role in the diversification and distribution of the vegetation. Major vegetation zones of interest are steppes, forest-steppes and related shrublands. The steppe zone is marked with *Artemisia* steppes of the plains, tragacanthic/thorn-cushion steppes of the mountains and scattered intrazonal saline vegetation. Forest-steppes and related shrublands are dominated by *Pistachio-almonds* in dry foothills and by oaks-junipers on the mountains. The region is one of the richest in terms of biodiversity: the Irano-Anatolian biodiversity hotspot covers most of the Middle East and neighbors the Caucasus hotspot. It is an endemism center pronounced with more than 4000 endemic plants and some butterfly genera. Furthermore, it supports populations of several endangered large herbivores as well as top predators such as the leopard. Livestock keeping is the major land-use activity on grasslands. Grasslands are mostly managed extensively around villages and in the form of large-scale transhumance in highlands. Shrubs and trees are harvested for fuel, construction material for local use and charcoal production. Unregulated (unsustainable) grazing, conversion to croplands, afforestation with non-native tree species, mining and energy production projects are the major threats that cause habitat degradation, fragmentation and loss. The protected areas cover ca. less than 15% of each country and their efficiency to fulfill conserve priorities are under question.

Delimitation and Physiogeography

The region in the focus of this article is the Middle East (ME) and the Caucasus (C). Although a wide range of delimitations is applied for the ME, we adopt a common approach which also provides consistency in ecological conditions: In this article, ME extends in Asia, from the Anatolian Peninsula of Turkey in the north to Syria, Lebanon, Palestine, Israel, Jordan and Saudi Arabia in the south; and Iran and Afghanistan to the east. Among those countries, we focus on the ones with a large area of grasslands and shrublands of non-Mediterranean origin; therefore we focus on the land within the borders of Iran, Iraq, Afghanistan, Jordan, Syria, and Turkey (Fig. 1). The Caucasus region, on the contrary, is well agreed to extend from northeast Turkey, Georgia and neighboring lands of Russia, Armenia to Azerbaijan. Within those countries, we focus on steppes and related vegetation and further exclude the land covered by Mediterranean, desert, closed-canopy temperate forest and alpine vegetation. With a rough estimate, this land covers 2 million km² (Fig. 1, based on ecoregions in Olson et al., 2001).

The region lies like a bridge between the Mediterranean Sea, Black Sea, Caspian Sea, Persian Gulf and Red Sea. The Turkish-Iranian Plateau, from East Anatolia to Caucasus, is lifted from the Neo-Tethys Sea after the Middle Miocene following the initial Paleogene Arabia-Eurasia collision and since then shaped by mantle-derived collision magmatism (Neill et al., 2015). The elevation is above 500 m in depressions, between 1000 and 3000 m in high plateaus but more than 4000 m at the peaks. The region is lined with several mountain chains of the Alpine-Himalayan orogenic belt: North Anatolian and Taurus, Lesser Caucasus and Greater

Fig. 1 The Middle East and the Caucasus with countries on the focus of this article labeled. Country borders were shown in red. The map was colored to show lowlands (green), plains and rolling hills (yellow), mountains (brown) and mountain peaks (white) and water bodies (blue). The lake layer (in turquoise color with black lining) was obtained from NatureEarth. The map shows an area between ca. 23°–43° latitudes and 25°–73° longitudes in north orientation. Scale:1:16,000,000.

Caucasus, Zagros and Alborz Mts. aligned on the north and west borders of Iran and finally Hindu Kush of Afghanistan. Rolling hills and scattered mountains are common as well. Long rivers (e.g., Euphrates, Tigris, Çoruh, Amu Darya, and Helmand) fracture the topography. The region is rich in water bodies with many scattered lakes but few large ones such as Van Gölü (3755 km²) of Turkey, Urmia (5200 km²) and Bakhtegan (3500 km²) of Iran, most of which are saline lakes. In the central parts of the basins, the accumulation of evaporitic minerals led to the formation of vast expanses of salt soils and permanent or ephemeral salt lakes.

The region has a complex geological structure, leading to high plant diversity. The geological formations are very different in origin (plutonic, volcanic, sedimentary, metamorphic), age (Precambrian to Quaternary) and composition. The major bedrock types are soft bedrock-chalk, clay marl in central Anatolia, basic igneous rocks in eastern Anatolia, neritic limestones and undifferentiated continental clastic from Southeastern Anatolia to the north of the Arabian Peninsula (Okay, 2008; General Directorate of Mineral Research and Exploitation, 2015), various limestones in western and NE Iran; calcareous, siliceous and volcanic rocks in central Iran and the Alborz; flysch in the Makran Range of southeastern Iran and volcanic complexes in NW Iran. The soils of the ME&C, generally of low productivity, represent six major soil types: soils of arid regions with low organic content dominate central Anatolia and Mesopotamia (xerosols). Lithosols, less than 10 cm deep on coherent hard rocks, dominate the Turkish-Iranian Plateau and Afghanistan (FAO/UNESCO, 1971–1981). Highlands of this zone on the south are covered with calcic and luvic kastanozems: humus rich brown soils of the arid zone but not as productive as chernozems of the Russian steppe belt. Cambisols cover relatively small area at alluvial zones. They lack a layer of accumulated clay, humus, soluble salts and iron. Along the Black Sea Coast where semi-natural grasslands do occur, vertic luvisols dominate. Luvic arenosols, sandy-textured soils that lack any significant soil profile development, cover southwest of Afghanistan.

According to Köppen-Geiger classification, three major climate types occur in the region—excluding deserts (Kottek et al., 2006): (i) a warm Mediterranean-like temperate climate dominates the region. It prevails in most of the Anatolian periphery, extending to western Syria and western Iran. The summers are dry and hot and winters are rainy and mild. (ii) An arid climate with less precipitation and harsher winter conditions prevails in depressions of the ME and Azerbaijan. (iii) On the highlands of east Anatolia, Iran and Afghanistan, a colder climate prevails which is called “snow zone.” Summers are comfortably cool and there is a permanent snow cover on mountains. In Lesser and Greater Caucasus, a fully humid snow climate is experienced. Toward east of Afghanistan, the climate is affected by monsoons. Having said that, we should also mention that Rivas-Martínez et al. (2011) classify the whole region under the effect of Mediterranean macro-climate except northeast Anatolia, Lesser and Greater Caucasus and southern coasts of the Caspian Sea, where a temperate climate prevails.

Origin of Grassland and Shrubland Communities

World-wide expansion of grasslands was associated with increased aridity between 8 and 6 MaBP, a decline in woodlands due to fires, and coevolution of mammals adapted to grazing and open habitats (Anderson, 2006). Those enabled grassland to replace once-forest covered habitats. Onwards, grasslands and forests replace one another due to climatic oscillations and human interventions. During the last glacial period (30,000–15,000 calibrated years before present) in Anatolia for example, the climate was generally cold and humid and therefore the northern Anatolia was covered by forests of *Pinus* spp. in cool places but of *Fagus*, *Alnus*,

Quercus, and *Pistacia* under warmer conditions. But under cold and dry conditions, steppes of *Artemisia*, Chenopodiaceae and Poaceae dominated the land (Şenkul and Doğan, 2013).

Under current climatic conditions, it is expected that sites with more than ca. 500 mm annual precipitation are covered by closed-canopy forests. Within this zone, mesophilic semi-natural grasslands are found in sites of forest clearance or depending on edaphic conditions. Areas with less than 300 mm annual precipitation are expected to be covered naturally by treeless steppes and desert-steppes (Fig. 1). Following the definition in Wesche et al. (2016), steppes are the vegetation types dominated by herbs, mainly grasses and other graminoids, sometimes with a significant admixture of chamaephytes, in arid and semi-arid climates. In transition between natural steppes and closed-canopy forests, forest-steppes cover large areas as exposure- or soil-related mosaics or open woodlands (Erdős et al., 2018). In steppes and forest-steppes; scrublands composed of dwarf-shrubs of *Artemisia* or of thorn-cushions as well as shrubby forms of trees belonging to the forest-steppes are common. Today, vegetation types of the region show distribution patterns different from naturally limited: steppes of the ME and Caucasus cover larger areas than naturally limited due to continuous deforestation and grazing activities. As a result, the vegetation has many elements resistant to grazing. Furthermore, the dwarf-shrub communities of *Artemisia*, naturally making up desert-steppes of very dry areas on depressions, are more widespread due to grazing. Oak woodlands are one of the most common type of forest-steppes. Based on pollen records, Asouti and Kabukcu (2014) claim that low-diversity, even aged shrubby oak woodlands of the ME are actually not natural but replaced natural semi-arid savannah grasslands by sheep grazing and harvest practices. Furthermore, forest-steppes have shrunk due to deforestation activities. Wild orchards, scattered fruit trees on rocky outcrops or arable fields, are very common in the region. They were thought to be remnants of preceding forest-steppes but it was shown that they were there before oak expansion and the dominant shrubs of the wild orchards are not common in forest-steppes (Woldring and Cappers, 2000). As a summary, most of the vegetation has been largely shaped by human activities.

Typology of Communities

The vegetation types in the focus of this article are major natural and semi-natural grassland and shrublands. We excluded Mediterranean vegetation, wetlands, sparsely vegetated areas (less than 10% cover), humid forests, alpine vegetation, intensified grasslands, ruderal and segetal vegetation. We put emphasis on steppes and forest-steppes but also briefly mention saline and semi-natural grasslands. We classify grasslands and shrublands of the region into five major groups: intrazonal saline vegetation in lowland depressions, three zonal vegetation types: plain steppes, montane steppes, forest-steppes and related shrublands, and azonal mesophilic semi-natural grasslands (Figs. 2 and 3). Of those; primary or secondary origin is common in the region. The elements of those different vegetation types can be seen together in transition zones as well as in many other places due to human effects.

Saline Vegetation

Salty hydromorphic alluvial soils around saline lakes have high salt content (up to 10% NaCl and Na₂SO₄) and support halophytic vegetation (Fig. 2C). Salinity and moisture are two important ecological drivers shaping halophytic vegetation (Akhani, 2004, 2006). The saline vegetation is species poor with mean number of species 6–15 per 64–100 m² area but can be rich in endemic species (personal observations). Soils with moderate salt and low moisture content are dominated by grasses (*Puccinellia koeieana* and to a lesser extent *P. convoluta*), or annual forbs (e.g., *Suaeda cucullata*, *S. carnosissima*) and accompanied by succulent forbs. In hypersaline places close to both permanent water and salt crust, *Frankenia hirsuta* becomes dominant together with *Petrosimonia brachiata*, *Salsola* spp. (e.g., *S. stenoptera*) and *Limonium* spp. Perennial forbs are generally absent and perennial grasses have underground organs to survive (e.g., *Cynodon dactylon*). Plant communities of high water tables are *Juncetea maritime* (halophytic grassland and herbaceous perennial sedge communities belonging to genera *Puccinellia* and *Juncus*), *Tamaricetea ramosissimae* (*Tamarix* communities) and *Haloxylon-Salsoletea tomentosae* (halophytic shrubby communities on salty and dry soils) (Akhani, 2004). As the salinity increases, the share of perennial forbs decreases; and annual grasses and succulent plants increase (Çetik, 1985).

Plain Steppes

We focus on steppes on plains (ca. 900–1200 m elevations) and group them into desert-steppes and treeless steppe grasslands. Desert steppes occur in the driest depressions of the region and lowlands neighboring the desert zones. Desert-steppe vegetation is dominated by *Artemisia*; herbs or dwarf-shrubs of Asteraceae that are usually aromatic and bluish-silvery in appearance (Fig. 2A). Naturally confined to steppe zone, this vegetation type extends to mountains as a response of grazing eliminating natural perennial grasses and other herbs (Zohary, 1973; Walter and Breckle, 1985; Frey and Probst, 1986). Density and floristic composition of these scrublands are influenced by edaphic factors, annual precipitation and duration of the dry season, elevation and erosion (Frey and Probst, 1986). Some dominant species are *Artemisia fragrans* in central Anatolia (Çetik, 1985); *A. sieberi* (referred as *A. herba-alba* s.l. in the old literature), *A. kopetdaghensis*, *Seriphidium quettense* (valid name for *A. quettensis*), *A. lehmaniana* and *A. santolina* in southeast Anatolia, Iran to Afghanistan (Breckle, 2007). In rainy years and particularly toward mountains, species richness of these steppes is increased to around 45 species in each 25 m² plots in Iran (Akhani, 1998). In plain steppes, the

dominant *Artemisia* is accompanied by common species of treeless steppe grasslands such as *Thymus* and *Stipa* spp., *Poa bulbosa*, *Festuca valesiaca* and *Noaea mucronata* (Akhani, 1998).

Treeless steppe grasslands naturally occur in sites with ca. 300 mm annual precipitation but can extend in more humid lands due to anthropogenic influences. This vegetation is mostly destroyed and highly degraded except in protected areas. It is dominated by perennial grasses of *Bromus tomentellus*, *Festuca valesiaca*, *Stipa* (*S. lessingiana*, *S. pulcherrima*, *S. hohenachkeriana*, *S. holosericea*, *S. tirsia*, *S. pennata*), *Koeleria pyramidata* (valid name for *Koeleria cristata*), *Elymus hispidus* accompanied by *Thymus* spp. (e.g., *T. leucostomus* var. *leucostomus*, *T. sipyleus* ssp. *rosulans*, *T. longicaulis*, *T. kotschyanus* var. *kotschyanus*, *T. pubescens*, *T. transcaucasicus*) and forbs from a diversity of plant genera e.g., *Achillea*, *Alyssum*, *Ajuga*, *Anthemis*, *Convolvulus*, *Euphorbia*, *Fumana*, *Galium*, *Genista*, *Hedysarum*, *Helianthemum*, *Hypericum*, *Linum*, *Marrubium*, *Nepeta*, *Onosma*, *Onobrychis*, *Phlomis*, *Silene*, *Salvia*, *Scutellaria*, *Teucrium*, *Veronica*, etc. (Fig. 2B as an example). A peculiar steppe type of the Lesser Caucasus is dominated by wild wheat species, i.e., *Triticum boeoticum*, *T. araraticum* and *T. urartu*. Overgrazed sites are marked with presence of many unpalatable, spiny or grazing-resistant species such as *Noaea mucronata*, *Peganum harmala*, *Gundelia tournefortii*, *Eryngium campestre* and several species of *Verbascum*. In Georgia, the dominant species of steppe vegetation is *Bothriochloa ischaemum*, a representative of the subtropical-tropical *Bothriochloa* genus. Typologically, they are very diverse and include vegetation units of *Glycyrrhizieto-Bothriochloeta*, *Bothriochloeta ephemerosa*, *Festuceta-Bothriochloeta*, *Stipa-Bothriochloeta*, etc. (Nakhutsrishvili, 2013).

Montane Steppes

Montane steppes are the natural vegetation of wind-swept slopes of above timberline to subalpine zone (1800–3500 m a.s.l.) (Kürschner, 1986), today they occur extensively in the montane zone (1200–1800 m a.s.l.) and replace forest-steppes, i.e. the potential vegetation of the zone, following disturbances. It is dominated by tragacanthic (thorny cushion-forming dwarf shrub form) or soft-leaved plant species (Zohary, 1973; Djmalali et al., 2011). Montane steppes can have a substantial amount (up to 30% cover) of shrubs and trees of the forest-steppes. Tragacanthic shrubby vegetation is one of the most important features of high mountains zone throughout the Middle East and SW Asia and very species-rich (Fig. 2D) (Zohary, 1973; Frey and Probst, 1986). The most common genera are *Astragalus* (e.g., *A. gummifer*, *A. microcephalus*, *A. lagopoides*), *Acantholimon*, *Acanthophyllum*, *Onobrychis cornuta*, *Gypsophylla*, *Minuartia*, *Ononis*, and *Arenaria* spp. On some volcanic highlands of Iraq, east Anatolia and Armenia, giant umbellifers

Fig. 3 Shrublands of the region. (A) Woodlands in south of Iran (a mixture of pistachio and almond vegetation). (B) Oak-juniper shrubland, Kayseri, Turkey. (C) Zagros forest-steppes of oaks, Iran. (D) Open woodlands in south of Armenia with *Quercus araxina*. (A) Photo by A. Naqinezhad. (B) Photo by D. Ambarli. (C) Photo by A. Naqinezhad. (D) Photo by A. Aleksanyan.

becomes dominant or co-dominant such as *Prangos* spp. (Prangeto-Astragaletum) accompanied by *Eryngium* sp., *Eremopoa persica*, *Thlaspi* spp., and *Alyssum* spp.. Protection from grazing pressure was shown to decrease the cover of tragacanthic species and increase the grasses such as *Festuca valesiaca* and *Dactylis glomerata*. Some examples of common forb genera are *Thymus*, *Salvia*, *Phlomis*, *Achillea* and *Verbascum*. Wild fruit trees (*Pyrus elaeagnifolia*, *Crataegus monogyna*, *Prunus cerasus*, *Rosa* spp. etc.) scattered in arable fields are common in montane steppes and rocky outcrops.

Forest-Steppes and Related Shrublands

The potential vegetation of sites with more than ca. 400 mm annual precipitation is forest-steppes which lost most of its natural vegetation due to destruction for cropland and hunting, and extraction of fuel and construction material. For example, forest-steppes in inner Anatolia cover 0.7% (2369 km²) of the land which is less than half of its potential area (Ambarli et al., 2016). The vegetation corresponds to one out of nine forest-steppe types of the Palearctic: the Middle East (Erdős et al., 2018). Within that, we differentiate two major vegetation types: xerophytic communities dominated by pistachio-almond communities mostly in lower elevation and oak-juniper communities on more humid parts. The communities can occur in the form of woodland, i.e. woody vegetation in which tree cover is between 10–40% due to aridity or degradation. Degradation causes those two plant community types to occur also in shrub form, i.e. woody plants with less than 2 m height in general and with several stems growing from ground level. Furthermore, shrublands of *Rhododendron*, typical for forest understory, cover large areas in subalpine zone of the Caucasus and the Black Sea region.

Pistachio-almond shrubby steppes occur between lowland *Artemisia* dominated semi-desertic steppes and thorn-cushion formations of the upper mountains (Zohary, 1973). The dominant species are *Prunus scoparia* (valid name of *Amygdalus scoparia*), *Pistacia khinjuk*, *P. atlantica*, *P. terebinthus* subsp. *palaestina* (SE Anatolia), *P. vera* (Afghanistan), *Amygdalus bucharica* (Afghanistan), *Cercis griffithii* (west Afghanistan) and *Crataegus* spp., *Pyrus* spp., *Cotoneaster* spp., *Rhamnus pallasii*, *Daphne mucronata*, *Acer monspessulanum* and *Fraxinus angustifolia* (in the Caucasus).

Oak and juniper formations, on the other hand, are widespread on the mountain zone (Mayer and Aksoy, 1998; Sagheb-Talebi et al., 2003, 2014; Breckle, 2007). Dominant species are *Quercus pubescens*, *Q. infectoria*, *Quercus brantii*, *Quercus petraea* subsp. *pin-natiloba*, *Q. libani*, *Juniperus oxycedrus* and *J. excelsa* (Zohary, 1973; Assadi, 1989; Sagheb-Talebi et al., 2003; Breckle, 2007; Kürschner

and Parolly, 2012; Akan, 2019). Wild orchards (sensu stricto Woldring and Cappers, 2000) are common. Carpet like formations of *Juniperus communis* and *J. sabina* cover montane and subalpine zones (Ravanbakhsh et al., 2016; Assadi, 1989; Akhani, 1998). Those are accompanied by shrubs like *Berberis integerrima*, *Rubia florida*, *Lonicera nummulariifolia*, *Cotoneaster ellipticus* (valid name for *C. nummularius*), *Cerasus microcarpa*, and *Rhamnus pallasii* in the Caucasus. Oak-juniper woodlands are mixed with pine trees (*Pinus nigra* subsp. *pallasiana* and *Pinus sylvestris*) at high elevations in Turkey. Xeric woodlands merge with *Quercus baloot* or *Pinus gerardiana* evergreen woodlands in east Afghanistan (Breckle, 2007). Human intervention results in lower canopy cover and height and changes in vegetation structure, e.g. shrubby form, and composition (Akman, 1974; Çetik, 1985).

Forest-steppes can include a diversity of trees. Elements of Mediterranean vegetation or of humid forests are found under special micro-climatic conditions. It is common to see open shrublands of *Acer*, *Lonicera*, *Cerasus* and *Cotoneaster* in mesic valleys. Caucasian forest-steppes occur with *Acer monspessulanum* subsp. *ibericum*, *Celtis glabrata*, *Pyrus salicifolia*, *Prunus fenziiana*, *Punica granatum*, several wild fruit trees and many other Mediterranean elements (Aleksanyan, 2012; Fayvush and Aleksanyan, 2016). Succession scrubs of *Paliurus spina-christi*, *Jasminum fruticans*, *Rhamnus* are common features of dry foothills in valleys and along some seasonal rivers and streams (Memariani et al., 2016). In Armenia, they get the special name *shibliak* and occur almost in every mountain belt, except in the highlands. About 25–30 species contribute to the formation of *shibliak* including both mesophilic and xerophilic species such as *Berberis vulgaris*, *Cotinus coggygia*, *Punica granatum*, *Carpinus orientalis*, *Crataegus orientalis*, *Lonicera iberica*, *Rhamnus pallasii*, *Caragana grandiflora*, *Atraphaxis spinosa*, *Ephedra major* subsp. *procera* (Aleksanyan, 2012). *Rhus coriaria* communities occur sporadically in forest-steppes of Iran as well as inner Anatolia (Sabeti, 1976). Even Saharo-Sindian species occur in a subtropical, savanna like ecosystem along the Persian Gulf and the Sea of Oman (see Zohary, 1973; Léonard, 1989; Djamali et al., 2011): Its woody members are *Acacia* spp., *Albizia lebbekii*, *Calotropis procera*, *Capparis decidua*, *Dalbergia sissoo*, *Moringa peregrina*, *Nannorrhops ritchieana*, etc. (Assadi, 1989; Sagheb-Talebi et al., 2014).

Mesophilic Semi-Natural Grasslands

Semi-natural grasslands occur in the humid zones under the effect of the Black Sea and Caspian Sea. Anthropogenic managed pastures, meadows and tall-herb meadow fringes on fertile deep soils at low and mid-elevations (rarely also high elevations), humid grass-rush meadows, tall-rush wetlands, patchy green wet meadows and fens in mountain slopes and riverbanks are among types of such grasslands (Ambarlı et al., 2018). Although grasslands were degraded as a result of millennia of overgrazing, they still are of great importance in the high montane and subalpine zones, like in northern parts of Alborz Mts slopes in north Iran. Meadows and pastures are present in the northern slopes of Alborz Mts where the potential natural vegetation is the montane or submontane forests. Kelardasht, Kojour area and Golestan National Park are important examples. They can also occur due to abandonment of the cultivated lands or settlements within the forest (Akhani, 1998, 2005). In some areas of Iran, a well-developed vegetation dominated by *Elymus hispidus*, *Elymus elongatiformis*, *Cephalaria microcephala* and *Carex melanostachya* covers higher mountains and subalpine areas, where scattered *Acer* or *Crataegus* shrubs can also be seen (Akhani, 1998, 2005; Memariani et al., 2016). Grasslands of the northeast Anatolia which is used mainly for hay-cutting host tens of rare butterfly species and therefore they are prime butterfly areas of the country as well as Europe (Karaçetin and Welch, 2011).

Biogeography and Biodiversity

The ME and the Caucasus are in the Western Palearctic biogeographically. During the last Ice Age, species of the western Palearctic found refuges there: especially the Caucasus and the periphery of the Taurus Mountains of Turkey were refuge areas and then centers of adaptive radiation for several taxonomic groups such as grasshoppers, hedgehogs and brown bears (Hewitt, 2000). Several relict species do occur in the region such as *Rhodothamnus sessilifolius* and *Rhododendron caucasicum*. Owing to the diversity of abiotic conditions, land-use practices (see below), unique geological history and large size; the ME and the Caucasus host remarkable plant and animal diversity. The region lies at the intersection of three biodiversity hotspots (Regions with remarkably high percentage of endemic vascular plants (>1500) and low percentage of its original vegetation (<30%): Irano-Anatolian, covering most of the region, the Caucasus on the northeast, and the Mediterranean on the west (Mittermeier et al., 2011). Those are also part of the Global 200 Ecoregion network because of specific evolutionary processes and unique historical floral and faunal development (Nakhutsrishvili, 2013). The hotspots overlap with phytogeographical regions, i.e., regions with distinctive climate and flora (Takh-tajan et al., 1986): The Irano-Turanian region, marked with continental climate, covers most of the inner land. The Mediterranean region along the sea has a substantial effect on the flora. The Euro-Siberian region shapes the flora of the Black Sea and Caspian Sea coasts, and the Caucasus. Additionally, the Saharo-Sindian region covers southern parts of Iran and Iraq, extending to Saudi Arabia and Pakistan.

The Irano-Turanian region is a center of evolution and endemism for many plant genera (Kürschner, 1986; Manafzadeh et al., 2017) such as *Astragalus*, *Verbascum*, *Salvia*, *Acantholimon*, *Acanthophyllum*, *Cicer*, *Cousinia*, *Dianthus*, *Onosma*, *Echinops*, *Euphorbia*, *Gypsophila*, *Minuartia*, *Noaea*, *Onobrychis*, *Oxytropis* and *Scorzonera* (Zohary, 1973). Among those are the tragacanthic plants e.g., many *Astragalus* sp. and *Onobrychis cornuta*. Furthermore some endemic genera of the Irano-Turanian region are monotypic (i.e., genus with only one species), such as *Azilia*, *Mozaffariania*, *Kalakia*, *Elburzia*, *Zerdana* and *Zhumeria* (Noroozi et al., 2019). The grasslands of the ME have high cover of herbaceous species adapted to arid conditions; i.e., xerophytes e.g., *Thymus spathulifolius* (Fig. 4). The steppes represent a center for secondary adaptive radiation, giving rise to numerous groups of closely related, often vicarious,

Fig. 4 A selection of steppic species. (A) Steppe fritillary *Euphydryas orientalis* endemic to Turkey, (B) *Thymus spathulifolius* endemic to Turkey, (C) Chukar partridge *Alectoris chukar*, (D) Asia Minor ground squirrel *Spermophilus xanthopyrmnus*. Photographers: Didem and Hüseyin Ambarlı.

neoendemic species, explained with the recent neogenesis of Anatolia (Pils, 2013). As expected, the countries of the Irano-Turanian region hold the richest flora of the northern temperate zone compared to their sizes. Turkey has 9753 vascular plant species, ca. 30% of which are endemics (Güner et al., 2012). It is estimated that at least half of those endemics live in semi-arid inner part. More than 8100 vascular plant species are present in Iran with almost 30% endemics (Noroozi et al., 2019). Afghanistan is estimated to have 5000 vascular plant species with 25–30% endemic to the country (Breckle, 2007). The number of vascular plants in the Caucasus is as follows: 3800 for Armenia, 4500 for Azerbaijan and 4310 for Georgia (Ministry of Ecology and Natural Resources Republic of Azerbaijan, 2014; Ministry of Environment Protection and Natural Resources of Georgia, 2015; Ministry of Nature Protection of Republic of Armenia, 2014) with endemism ratios between 3% and 7%. The region is also a world center for agro-biodiversity, hosting wild relatives of many legume and cereal crops such as einkorn, emmer, barley and rye (Willcox, 2005).

The region is important not only for the floral elements but also for the fauna (Fig. 4): The ME&C is an endemism center for the genus *Erebia*, one of the most diverse butterfly genus of the Palearctic (Peña et al., 2015). Furthermore, Iran-Turan region is the center of diversification of a group of Lycenids, *Agrodiaetus*, with more than 120 species. The group has one of the highest interspecific karyotypic diversities known in the animal kingdom with an explosive speciation rate of 1.6 species per million years (Kandul et al., 2007). The countries hold extremely high diversity of butterflies, remarkably the Lycaenids (Blues). For example, Turkey is the richest in Europe with more than 380 species, 81 of which are endemics such as the steppe fritillary *Euphydryas orientalis* (Fig. 4) (Karaçetin and Welch, 2011).

The region holds the breeding bird fauna of a majority of the Western Palearctic habitats from semi-deserts to Caucasian forests (Rosalea, 1995). Furthermore, every year it hosts millions of migrating birds of the Palearctic as it has important passages: Flyways from East Asia to East Africa, Palearctic-African and central to South Asia pass through Bosphorus, Caucasus and over the Black Sea. More than 30 Ramsar sites, wetlands of global importance, serve as stopover or wintering grounds for birds (Ramsar Information Centre, 2019). The region is a home for several steppic bird species distinguished by cryptic coloring, ground nesting, tendency to walk or run and aerial displays such as several species of larks, Chukar partridge *Alectoris chukar* (Fig. 4), great bustard *Otis tarda* and little bustard *Tetrax tetrax*. The Caucasus hosts a regional-endemic bird species, the Caucasian Grouse (*Lyrurus mlokosiewiczi*) which lives in alpine and subalpine grasslands and humid shrublands of *Juniper* and *Rhododendron*.

ME&C is remarkable in wildlife: hosted lions, wild oxes, elephants a few centuries ago; it is still possible to see small herds of wild ungulates such as the Mouflon (*Ovis orientalis*), the ancestor of the domestic sheep, and more than 10 gazelle species, some of which are endemic to region e.g., Cuvier's Gazelle (*Gazella cuvieri*). Habitats support populations of large carnivores such as gray wolf (*Canis lupus*), brown bear (*Ursus arctos*) and leopards (*Panthera pardus*) that are extinct in neighboring biomes. Not only large mammals but also small mammals are abundant. Taurus Ground Squirrel (*Spermophilus taurensis*), Asia Minor Ground Squirrel (*Spermophilus xanthopyrmnus*, Fig. 4D) and Williams's Jerboa (*Allactaga williamsi*) are among many endemic small mammals of the region.

Land Use

Birth of agriculture is probably one of the major critical advancements in human history. The Fertile Crescent is one of four major centers of first farming where several cereal and legume crops were domesticated (Brown et al., 2009). This land extends from Palestine to Turkey and Syria; covering valleys and adjacent hills of Jordan, Tigris and Euphrates rivers. It is also the earliest for animal domestication, as early as 11,000 calibrated years BP for cattle and sheep (Zeder, 2008). Since then, the region hosts the oldest civilizations of the Palearctic such as the Hitites, Romans, Seljuks, Persian, Byzantine and Ottoman. The oldest sanctuary of the world, Göbekli Tepe, where hunter-gatherers worshipped during the stone age, was discovered in the Fertile Crescent a few years ago (Schmidt, 2012). As a result, the habitats and its biodiversity are the earliest to be exposed to the anthropogenic effects of agriculture, domestication and settled life. The vegetation has continuously been shaped by humans: destruction by fires for opening croplands, hunting grounds and grassland management purposes; wood cutting for fuel and construction material, wars etc. Not only the locals but also migrating populations and trade along the Silk Road contributed to this effect.

The countries of the region have small economies except developing conditions in Turkey and Iran (Table 1). The share of labor in agriculture varies between 2% in Jordan and 79% in Afghanistan where most of the labor works in agriculture. Low productivity due to semi-arid conditions and prolonged summer droughts allow only for rangeland grazing in lowland steppes. In the more humid and productive highlands, hay making and transhumance grazing are also commonly practiced. A total of 35 million cattle held in countries of the region represent ca. 2.3% of the world total (Table 1). The ME region is a milk exporter with the total production of 25 million tons in 2008 (Maitah and Smutka, 2013). Livestock keeping is usually coupled with cereal and pulse production for subsistence or semi-subsistence in family farms, except for areas with very cold winters or dry summers (Karagöz, 2006). Today, most of the grazing takes place around settlements. Sheep is the common livestock of the lowland plains and it is replaced by cattle on highlands and by goats in rocky mountains. Nomadic life, disappeared in Turkey, is still common in Iraq, Iran and Afghanistan. Transhumance grazing, seasonal migration of livestock on fixed historical routes to productive meadows, is common in the highlands.

Shrublands in the focus of this article are accepted to be of low wood productivity due to arid conditions. Today, they are mostly used by local people for fuel and construction material. Another common use of oaklands is charcoal production for ovens and barbecue: Coppice oak stands are cut rotationally, e.g., every 20 years, by wanderer families. This activity maintains the oaks in a shrubby stage. Oak nuts are used to make some local bread, so-called "Kalg." It is specifically eaten for stomach pains and gastrointestinal problems (Mosaddegh et al., 2012).

There are other common extractive uses of grasslands and shrublands. Those are hunting areas especially for small game animals such as hares, partridges and foxes, although some of such activities can be illegal. Collecting wild plants for medicinal or commercial purposes is common among local people. Bulbous plants are the target of illegal collection e.g., *Orchids* for ice-cream making and other bulbous plants for flower markets. An extractive use of steppes is removal of tragacanthic *Astragalus* species e.g., *A. microcephalus*. Those species have multiple uses: They are widely collected for fuel, fodder, medicinal plants, and even cleaning stuff. They are burned to heat shepherds during cold nights in rangelands. Tragacanth gum produced by *A. gummifer* (Milkvetch) is collected widely to be used as thickener in confections, salad dressings, sauces or for medicinal purposes (Kadioğlu et al., 2008). As a result, *Astragalus* steppes are degraded and open to erosion and desertification. Bee keeping is a non-extractive land use widely practiced in grasslands as well as forests. A kilogram of honey of average quality is worth more than 20 Euros and the same amount of honey produced in traditional ways in the sup-alpine meadows of the Black Sea region costs as much as 200 Euros.

Table 1 Population, labor force and its share in agriculture sector, gross domestic product (GDP) and cattle numbers for the Middle East and the Caucasian countries in focus of this article.

Country	Area (km ²)	Population (millions)	Labor force (millions)	Agriculture in labor force (%)	GDP (billion US\$)	Cattle number
Afghanistan	652,860	33.3	7.9	79	21	5,349,000
Armenia	29,743	2.9	1.4	18	11	661,003
Azerbaijan	86,600	9.9	5.0	6	53	2,442,373
Georgia	153,910	3.7	2.0	9	14	1,128,800
Iran	1,745,150	80.8	27.4	16	386	8,670,000
Iraq	435,050	32.6	9.7	22	177	2,780,000
Jordan	89,320	7.9	2.5	2	38	69,100
Syria	185,180	18.0	4.8	17	40	NA
Turkey	785,350	79.8	31.9	18	860	13,916,924
Total	4,163,163	269	93	–	1600	35,017,200

Note that only countries with large share of non-Mediterranean grasslands and shrublands are included.

Threats and Conservation

Due to various unsustainable land-use activities acting on the biodiversity of the ME&C, many species are threatened: for example, among the 10,930 species of vascular plants, birds, butterflies, mammals and herptiles distributed in Turkey, 1130 species were found to be living predominantly in steppic environments and being classified either as threatened, near-threatened or data deficient at the national level, if not globally (Ambarlı et al., 2016). In Armenia, from 3800 vascular plants, 452 are included in Red Book of Armenia among which many species are adapted to grasslands (Tamanyan et al., 2010). Among the major threats acting in recent times are overgrazing, afforestation, illegal harvest and over-exploitation of wild plants and animals, climate change and unsustainable exploitation of minerals and fossil fuels. Those threats act in similar ways in different countries.

Overgrazing is a major problem throughout the region. Almost half of the land is not suitable for livestock production and local livestock densities are usually too high for low-productivity pastures (see country summaries in Table 1), except highlands in the eastern Anatolia, Iran and the Caucasus. For example, by the beginning of the 1990s due to plowing the mountain steppes and intensive grazing on the remaining, steppes of the Caucasus, which occupy from 1200–1300 to 1800–2000 m above sea level and higher, were limited mostly to steep and strongly stony slopes (Fayvush, 2000; Fayvush and Aleksanyan, 2016). As a result, more than 60% of the land here was more or less eroded. Natural populations of wild relatives of crop species are threatened due to deterioration and fragmentation of their habitats, overgrazing and desertification. The indigenous breeds and populations of domestic animals are also threatened due to hybridization with non-indigenous breeds, transfer of diseases and shrinkage of populations due to abandonment of grazing in some places. E.g., Hybridizing with Swiss and American breeds causes erosion of genetic resources of Caucasian gray cattle breeds and threatens the local populations (Food and Agriculture Organization of the United Nations, 2019).

The most important factors affecting the structure of the grasslands in the Middle East are grazing and fuel collection. They allow penetration and expansion of many ruderal, shrubby and tragacanthic vegetation in natural communities (Zohary, 1973). Over the millennia a change of species composition has occurred. Desertification, i.e., decrease in total vegetation cover, disappearance of perennial grasses and herbs but increase in dwarf shrubs as a response to grazing, is a common problem of the ME. The nomadic grazing of herds over millennia has markedly changed the face of the vegetation of Iran. The present broad distribution of vegetation units dominated by thorn shrubs, dwarf scrub, or thorn cushions is assumed to have resulted from overgrazing. The original vegetation was shrunk, leading to the dominance of poisonous and unpalatable species like thorn cushions (antipastoralism, antipyrism). As Zohary (1973) pointed out, two processes of “ruderalization” and “tragacanthization” of the steppe is perhaps one of the most striking features in the dynamics of the *Artemisia* communities in most parts of Iran. This formation becomes more species rich (particularly with grass species like *Stipa hohenackeriana*), when protected from grazing and human interference. Conservation of some steppes and other grasslands provide the opportunity for developing original grasslands with less proportion of thorn-cushion plants due to grass species increasing competitive advantage. This situation is well observed in places like Golestan National Park or some long-time protected regions of northern slopes of Alborz (e.g., Golestanak Protected Area) (Akhani, 1998, 2005, personal observations). In Golestan National Park with a long history of protection, only few thorn-cushion species like *Onobrychis cornuta* and *Acantholimon raddeanum* occur along with many grass species such as *Festuca valesiaca*, *Stipa lessingiana*, *Poa densa*, *Poa bulbosa*, *Bromus tomentellus* and *Koeleria macrantha*.

Afforestation is a popular trend in areas that were formerly forest-steppes. Usually trees that do not occur naturally in a site are planted, not the native trees. Some examples are *Pinus nigra*, *Pinus sylvestris*, *Acacia* spp., and *Ailanthus altissima*. As a result, sites with rare plant and animal populations are destroyed. For example, in Turkey, the Forestry Department planted more than 24,000 km² only between 2008 and 2012, and most of the afforestation sites were steppes where several endemic plant and butterfly species live (Ambarlı et al., 2016). Planting non-native plants such as *Ailanthus altissima*, *Populus* spp., *Pinus* spp., *Cupressus* spp. and more recently *Paulownia tomentosa* for ornamental purposes is starting to cause invasive species to be an issue in forest-steppes of Iran.

Conversion to cropland was a threat in the past which replaced steppes and forest-steppes. Irrigation maintained by several dams promoted large-scale conversions in the Mesopotamia. But this trend is not in increase any more. Land abandonment is reported to be a threat in neighboring European countries due to shrub encroachment and disappearance of the grasslands. Such a negative impact of land abandonment has not been reported from the ME&C. On the contrary, one study shows that abandonment allowed natural restoration of the overgrazed lands and supported richer biodiversity (Ambarlı and Bilgin, 2014). The Middle East has one of the highest rates of emigration due to harsh living conditions, impoverishment and armed conflicts. Since 2011, the world has witnessed the fleeing of millions from Syria, seeking refuge. The consequences of armed conflicts for nature have not been documented yet.

The region is among the most vulnerable to climate change (Lelieveld et al., 2012): Compared to the period between 1961 and 1990, it is estimated that the maximum summer temperatures will increase 3.5 °C–5 °C at the north of the region but 1.5 °C–3.5 °C at the south in the period between 2040 and 2069. In the same period, number of dry days will increase by 5–20 days. This suggests strong shifts in species distributions and community composition, already stressed by existing growing conditions but also even harsher conditions for natural resource extraction and production.

Facing a wide range of threats, the steppes and forest-steppes of the region are under-represented in the network of protected areas. In Turkey, effective protected areas cover only 1.5% of those habitats and only 16.2% of the threatened and near-threatened species fall within the borders of protected areas of different categories (Ambarlı et al., 2016). Biodiversity conservation in Caucasian countries is implemented mainly in protected areas referred as specially protected nature areas, where 60–70% of the species composition of the flora and fauna is concentrated, including the overwhelming majority of rare and endemic species. In

Armenia the total territory covered by protected areas (3 state reserves, 4 national parks, 27 state sanctuaries and 232 natural monuments) is 387,054 ha, which comprises 13.1% of the total territory. Besides, there are also 2 protected landscapes and 1 biosphere reserve (Ministry of Nature Protection of Republic of Armenia, 2014). In Georgia, protected areas (14 state reserves, 11 national parks, 19 managed nature reserves, 41 natural monuments, 2 protected landscapes) occupy 600,597 ha area (about 8.6% of the country) (Ministry of Environment Protection and Natural Resources of Georgia, 2015). In Azerbaijan protected areas (9 national parks, 24 nature sanctuaries, 11 nature reserves) occupy 892,546 ha area (about 10.3% of the country) (Ministry of Ecology and Natural Resources Republic of Azerbaijan, 2014). Iran has a total of 203 protected sites, covering 10% of Iranian territory and types of grasslands and forests (Department of Environment, 2017). In Syria, there are 14 rangeland protected areas (Barkoudah et al., 2000). In general, effectiveness of the conservation in the protect areas of the ME&C it is not clear. In addition to the state protected areas, several sites are indicated as conservation areas of international importance such as important bird areas, important plant areas, key biodiversity areas, prime butterfly areas, Ramsar sites and sites of EMERALD network. There are national and international conservation efforts targeting specific species and habitats. For example, several FAO projects target strengthening protected areas with grasslands in the region. But evidence is needed for effectiveness of such projects. As the region itself is a biodiversity hotspot, further attempts are needed.

Abstract

For Northern Eurasia and, consequently, for Russia, temperate grasslands and shrublands are an obligatory element of a forestless landscape. They are present in all plain and montane biomes, forming natural and secondary (anthropogenic) communities, and occupy forestless spaces in the bounds of both the forest and steppe zones. In the forest zones, they are predominantly anthropogenic, locating in sites naturally occupied by forests (*Molinio-Arrhenatheretea* grasslands are specifically extensive and diverse here). Conversely, in the steppe zone, they are natural (*Festuco-Brometea* grasslands prevail). The total area of temperate grasslands is 920,000 km², of which 680,000 km² are used as pastures and 240,000 km² as hay meadows), and they are widely spread in all natural zones of Russia, especially within the forest zone (250,000 km²) and steppe zone (500,000 km² including steppes in mountain areas). The main distinctive features of their spread are small contour; diffusiveness; a strong anthropogenic transformation (of the steppe); and proneness to fires, desertification, etc. Biogeographically, the regions are so different that zonal-provincial variants can be identified. Grasslands are both zonal (steppes) and intrazonal (floodplain meadows). They are mainly composed of graminoids and forbs in different proportions, the composition and production of which change annually (fluctuations) and in perennial autogenous cycles (for example, “a year of grasses” or “a year of legumes”). A spatially extensive and diverse group comprises post-forest or post-agrarian watershed meadows, representing perennial stages of a progressive succession, which follow the pioneer stages. Their conservation (economically and sustainably optimal maintenance) depends on man, who has included them in the cycle of agrarian use as hay fields or pastures and, less often, uses for recreation and for conserving historical landscapes. A similar picture is observed for shrublands, which form both zonal (at watersheds) and intrazonal complexes with herbaceous vegetation. The most stable and spatially extensive shrublands are represented by two types. The first type are arctic and alpine thickets formed by Siberian dwarf pines (*Pinus pumila*), dwarf birches (*Betula rotundifolia*, *B. fruticosa* and others), and *Alnus alnobetula* subsp. *fruticosa*. The second type are steppe shrub thickets dominated by many species of genera such as *Caragana*, *Spiraea*, *Chamaecytisus* and *Prunus*. Shrublands on floodplains or clearing and burn sites are relatively quickly replaced with other kinds of vegetation during succession. The first inventory of grasslands in Russia was performed back in 1932–1938 by the outstanding vegetation scientist Leonty Ramensky (1884–1953), who was the first in the world to create so-called ecological scales (ecological indicator values), which, using data on the contribution of plant species in a community's composition, make it possible to assess habitat parameters (humidity, soil wealth, salinity, etc.). According to a recent phytosociological overview, the diversity of temperate grasslands and shrublands of Russia's plains comprises 18 classes, 35 orders, and 92 alliances for grassland communities and 4 classes, 5 orders, and 8 alliances for steppe shrublands. We highlight distinctive features of meadow and steppe ecology as well as the contribution of these habitats to the conservation of biodiversity, global climate regulation, and the formation of various ecosystem services, including use as hayfields, pastures, recreation and historical sites. Grassland and shrubland conservation and restoration in Russia are associated with the prospects to create a network of protected areas and with the restoration of steppe and meadow animal husbandry.

Boundary Delimitation and Area Physiography

Russia is situated in the Northern Hemisphere, surrounded by seas of the Pacific (the Bering Sea, the Sea of Okhotsk, and the Sea of Japan), Atlantic (the Baltic and Black seas and the Sea of Azov), and Arctic (the Barents, White, Kara, East Siberian, Laptev, and Chukchi seas) oceans, and has the longest coastline in the world (37,653 km). It lies in the North of Eurasia, occupying the larger part of Eastern Europe and the entire northern part of Asia. The conventional border between the country's European and Asian parts runs along the Urals.

The northernmost point of Russia is Rudolf Island (Franz Josef Land, 81°51' N); the easternmost, Big Diomed Island in the Bering Strait (169°0' W); the southernmost is at the border with Azerbaijan (41°11' N); and the westernmost is on the Vistula Spit of Gdańsk Bay of the Baltic Sea (19°38' E). The extent of the country from west to east is 10,000 km and from north to south, over 4000 km. The national area is a little more than 17,000,000 km².

According to some estimates the area of Russia's temperate grasslands is 7–10% of the national territory (White et al., 2000). It is quite concurring with official data of the land statistics of Russia (Rosreestr, 2013). Officially, grasslands in Russia occupy an area of 920,000 km² (ca. 5.5% of the national territory), including 680,000 km² counted as natural pastures and 240,000 km² as hay meadows. Large shrub thickets in the Russian land statistics are included in the "forest lands" category and occupy about 750,000 km² of the Forest Fund lands (Governmental Report, 2017).

The diffused character of the current distribution of natural shrub and grass vegetation is obvious from its reflection by variously scaled maps. On the map of Russia (see Map 2), for example, it occupies a continuous area within the steppe biome only in the Caspian Depression and in the south of Siberia. In the forest biome, meadows and shrublands are represented as large blocks mostly in the periphery of the area at the northern and southern boundaries, where their postforest character is obvious.

More than 70% of Russia's territory consists of upland and lowland plains. The western part of the country is within the vast East European Plain with its lowlands (the Upper Volga Lowland, Caspian Depression, etc.) and uplands (the Valdai Hills, Central Russian Upland, Volga Upland, etc.). The Ural Mountains separate the East European Plain from the West Siberian Plain; east of it lies the Central Siberian Plateau, continuing into the Central Yakut Lowland and then the Kolyma and Yana-Indigirka lowlands. Low mountains and foothills of Caucasus, Ural, Altai, Sayans, Baikal and Transbaikalia, and Far East constitute the main part of other Russian areas.

Extensive areas of temperate grasslands and shrublands formerly were presented on all the plains and low mountains in the zone of temperate climate (Figs. 1–3, Map 1). However, the actually existing tracts of grasslands and shrublands cover no more than 10% of the area of the forest and steppe zones (Map 2). Their area and spread within the forest zone vary from year to year and in perennial cycles owing to two major causes: progressive successions and involvement in economic use (ploughing and so on).

Significant areas of wet grasslands and shrublands are associated with rivers and wetlands. Russia has the world second largest (next after Brazil) amount of fresh water (FAO, 2003). Surface waters occupy 12.4% of primarily plain part of the country's territory, with 84% of surface waters being concentrated east of the Urals. Large tracts of floodplain ecosystems are scattered over the forest and steppe biomes in the floodplains of the Volga, Pechora, Kama, Ural, Ob', Irtysh, Yenisei, Angara, Lena, Yana, Kolyma, Indigirka, Anadyr, and other rivers.

Soils on plains are arranged in accordance with latitudinal zonality, as well as vegetation. Characteristic of the transitional tundra-forest zone (south of the northern boundary of the forest) are gleys and low podzolic or gley-taiga-cryogenic soils. About 65% of Russia's territory is within the forest zone. In its northern part, the soils are podzolic, and east of the Yenisei taiga-cryogenic soils. In the taiga subzone (especially in West Siberia), there are many bogs, primarily raised bogs (oligotrophic), and boggy forests. Peaty cryogenic soils often are presented here under grasslands and shrublands. Soddy podzolic soils underlie coniferous-broadleaved forests on the East European Plain, and gray forest soils underlie broad-leaved forests. They are also developed under oak forests in the forest-steppe subzone.

Characteristic of the steppe zone are chernozem soils (with a thick humus horizon of up to 1 m with humus content 4–10%). Dark chestnut (kastanozem), light chestnut, and brown soils, while saline soils are typical for more arid steppe subzones (dry steppe and deserted steppe). Over 50% of the global chernozem area is located in Russia.

Characteristic soils of intrazonal floodplain grasslands and shrublands are alluvial (i.e., affected by river, lake, or sea floods) and different in terms of duration. They are highly fertile due to annual silt ingress. This favors the development of highly fertile communities of meadows and shrublands (willow thickets) in floodplains.

The territory of Russia mostly lies north of 50° northern latitude (but about 8° more south in both the western and eastern ends of the country, in the Caspian shore of Caucasus and Far East). All the national territory south of the Polar Circle (N66.5°) is situated in the temperate climate, mainly belonging in the Köppen-Geiger climate types Dfb, Dfc, Dfd, BSk, Dwa, Dwb, Dwc, and to a lesser extent Cfa, Cfb, and BWk (Beck et al., 2018). Average January temperatures vary by region from +6 to –50 °C, and July temperatures, from 8° to 25 °C; precipitation is from 250 to 1000 mm per year. Permafrost (northernmost part of European Russia, Siberia, and the Far East) occupies 65% of the Russia's territory.

Climate diversity is determined by the zonal gradient, continentality gradient, and relief. The fullest spectrum of natural zones characterizes European Russia, where Arctic desert, tundra, forest tundra, taiga forest, mixed and broad-leaved forest, forest steppe, steppe, and semi-desert zones and subzones succeed one another from north to south. Almost the same climatic gradient (excluding semi-desert) can be found in the Far East. Moving inside of the Asian landmass, to Siberia and Central Asia, the climate becomes increasingly continental, and the number of natural zones decreases. The diversity of climatic conditions for the temperate grassland and shrubland area within the forest and steppe zones is shown in Table 1.

Biogeography, Flora, and Fauna

Biogeographically, the region lies entirely within the Boreal Kingdom, the Palearctic realm with sub-areas such as the Euro-Siberian taiga, European nemoral, East Siberian (Angarian), Eurasian steppe, Irano-Turanian, and Mediterranean regions.

According to M. Udvardy's classification (Udvardy, 1975), the following biomes are presented in Russia: tundras, temperate coniferous forests, temperate broadleaf forests, grasslands (steppes), deserts, and cold mountains of East Siberia. Cox and Moore (1993) identify only five biomes here: Arctic tundras, northern coniferous forests, temperate forests, temperate grasslands, and deserts. WWF recognizes six biomes: tundra; boreal forests/taiga; temperate broadleaf and mixed forests; temperate grasslands, savannas, and shrublands; deserts and xeric shrublands; and montane grasslands and shrublands (Olson et al., 2001). Steppes alone (without other temperate grasslands) often are considered as an entire biome (Wesche et al., 2016).

The biodiversity of Russia's temperate grasslands and shrublands is determined by their high landscape diversity, represented by the northern, middle, and southern taigas; larch forests and woodlands; coniferous–broad-leaved forests; broad-leaved forests;

Fig. 2 Plain steppes of Russia: (A) Belgorod Province, Photo by S. Titova; (B) Orenburg Province, Photo by A. Chibilev; (C) Altai Territory, Photo by I. Smelansky; (D) Transbaikalian Territory, Photo by I. Smelansky.

forest steppes; and meadow, typical, dry, and deserted steppes in zonal variant and specific variants on chalky, sandy, rocky, and salty substrates (Map 1), as well as by intrazonal ecosystems, such as different wetlands, floodplain and halophytic meadows. This is the reason for their exceptional landscape and ecosystem diversity, which is *a priori* the “receptacle” of high species diversity and the region’s biogeographic characteristic.

In regional floras of Russia’s forest and steppe biomes, vascular plants of grasslands and shrublands make up from 40–50 (taiga) to 80% (the subzones of meadow and typical steppes). In absolute values for a local flora (per 100 km²), there may be from 250 to 600–700 species, predominantly from the families (using the Takhtajan’ system of flowering plants taxonomy—Takhtajan, 2009) *Asteraceae*, *Poaceae*, *Brassicaceae*, *Fabaceae*, *Lamiaceae*, and *Ranunculaceae*; in floodplains additionally, *Cyperaceae*, *Polygonaceae*, *Juncaceae*, and *Chenopodiaceae*; and in xeric conditions (in steppes), *Scrophulariaceae*, *Caryophyllaceae*, and *Rosaceae* (Table 2). Among characteristically diverse genera in grassland communities are both graminoids (including such grasses as *Festuca*, *Poa*, *Stipa*, *Elytrigia*, *Bromopsis*, *Alopecurus*, *Dactylis*, *Deschampsia*, *Agrostis*, *Calamagrostis*, *Phleum*, *Bothriochloa*, *Koeleria*, *Milium*, *Hierochloa*, *Leymus*, *Arrhenatherum*, and also *Carex* and *Kobresia*), and forbs (such as *Centaurea*, *Trifolium*, *Lathyrus*, *Galium*, *Achillea*, *Crepis*, *Veronica*, *Filipendula*, *Thymus*, *Potentilla*, *Campanula*, *Rumex*, etc.). At the extreme positions of ecological gradients, grasses are replaced by other taxonomic groups: under high humidity, by sedges of the family *Cyperaceae*, and under growing salinization, by species from the family *Chenopodiaceae*. The alternation of the positions of families with the largest species diversity in the structure of the floras reflects the ecotopes of grassland communities by the gradients of humidity, soil wealth, and salinity. High requirements on the light regime are obligatory, distinguishing the ecosystems under consideration and their floristic composition from forests (Tables 2 and 3).

Bryophytes within grassland and shrubland communities are represented by the entire spectrum of the ecological groups of Russia’s mosses and liverworts: meadow (*Climacium dendroides*, *Thuidium recognitum*, *T. philibertii*, *Rhytidiadelphus squarrosus*), steppe (*Thuidium abietinum*, *Tortula desertorum*, *T. ruralis*), forest (*Pleurozium schreberi*, *Hylocomium splendens*, *Mnium* spp., *Rhodobrym roseum*, *Dicranum* spp., *Polytrichum* spp., *Hypnum* spp., *Mnium* spp.), and bog (*Sphagnum* spp., *Calliergon* spp., *Drepanocladus* spp., *Tomenthypnum nitens*, *Aulacomnium palustre* and others) species. Heliophilous and moderately hydrophilic moss species dominate, except for some steppe species, which can resist summer droughts.

Smelansky; (C) *Betula rotundifolia* shrubs (“ernik”), Altai Republic. Photo by I. Smelansky; (D) floodplain shrubs, Arkhangelsk Province. Source: www.pohody2.narod.ru.

Fungi of Russia’s meadows, steppes, and shrublands are also exceptionally diverse. Dominating among them are *Basidiomycota*: *Agaricus campestris*, *A. arvensis*, *A. bitorquis*, *A. xanthoderma*, *Coprinus comatus*, *C. atramentarius*, *Phaeolepiota aurea*, *Agrocybe dura*, *Marasmius oreades*, *Lepista saeva*, *Bovista nigrescens*, *Langermannia gigantea*, and others. In steppes, *Clavaria* species are also observed—*Clavaria argillacea*, *C. falcata*, *C. fragilis*, *Clavulina cinerea*, *C. coralloides*, *Clavulinopsis corniculata*, *Ramaria* spp., *Ramariopsis* spp., *Typhula* spp., and others. Their spatial distribution, as well as that of other groups of the biota, corresponds to the zonal gradient of heat and moisture (Shiryayev, 2018) (Table 3).

Based on floristic composition, Russia (excluding high mountains) is divided into the following floristic regions: Circumboreal, including the Northern European, Central European, Euxinian (the Black Sea coast), Caucasian (the Caucasus foothills), Eastern European, West Siberian, Altai-Sayan (the Altai foothills), Central Siberian, Transbaikalian, Northeastern Siberian, and Okhotsk-Kamchatkan Provinces; East Asian, including Manchurian (the Amur basin, Primorski Territory) and Sakhalin-Hokkaido provinces; Mediterranean, including the Crimea-Novorossiysk province; and the Irano-Turanian, including Turanian province (the Caspian Depression).

In different geographical units grasslands and shrublands occupy from 2% to 3% (steppes of central part of Russian plain or meadows of the northern taiga of European Russia) to 50–60% (the steppes, secondary meadows, and shrublands of the south of Siberia and the Far East) of the total area of the region.

Specific fauna of “open spaces” is characteristic for Russia’s grasslands and shrublands. Among insects the orders *Orthoptera*, *Homoptera*, *Heteroptera*, *Coleoptera*, *Lepidoptera*, *Hymenoptera*, and *Diptera* are dominating. Many of the insect species are obligatory associated with herbaceous forage plants and some of them lead in the elimination of grasslands primary production on large areas (for example, some locusts in steppes). Some of the typical steppe insects penetrate deep in the forest zone in Northeastern Siberia in the specific cold (cryo-arid) steppe habitats.

The characteristic mammals of steppe grasslands and shrublands of Russia’s plains are long-distant migrating antelopes—Saiga (*Saiga tatarica*) and Mongolian Dzeren (*Procapra gutturosa*). But these two species are surviving in small areas only, on the opposite ends of the steppe belt in Russia, Saiga in Caspian Lowlands and Dzeren in Transbaikalia. Actually widespread ungulates in

Map 1 Natural biomes and ecosystems of the Russia: (1) Polar deserts; (2) plain Arctic and subarctic tundras; (3) alpine tundras; (4) forest tundra, northern taiga, and larch woodlands; (5) middle taiga; (6) southern taiga and coniferous-broad-leaved forests; (7) plain and alpine broad-leaved forests; (8) ecosystems of middle mountains and highlands (subalpine and alpine meadows, shrublands, petrophytic groups, barren); (9) steppes; (10) desert steppes and deserts; (11) bogs; (12) floodplain complexes of large rivers.

Map 2 Map of the actual distribution of grasslands and shrublands on Russia's territory. Based on the analysis of ASTER, SPOT-Vegetation (1999–2012), and PROBA-V (2013–2015) images, a resolution of 300 m. Yellow means grasslands, mosaic herbaceous cover (> 50%); green, shrublands evergreen and deciduous (more than 15%).

grassland and shrubland habitats are the Roe Deer, *Capreolus capreolus* and *C. pygargus*, and common in Siberia is the Elk, *Cervus canadensis* (formerly Siberian Elk was considered as subspecies of *C. elaphus*). Ungulates are considered as keystone species in grassland ecosystems, their grazing and trampling forming grasslands in both evolutionary and ecological scales.

Other mammal grazers play a key role as ecosystem engineers in the grasslands, the colony-forming burrowing rodents and lagomorphs. In Russian grasslands the guild includes many species of the Sousliks (*Spermophilus suslicus*, *S. pygmeus*, *S. major*, *S. erythrogenys*, *S. dauricus*, *S. undulatus*), Marmots (*Marmota bobak*, *M. baibacina*, *M. kastschenkoi*, *M. sibirica*), Steppe Lemming (*Lagurus*

<i>Lamiaceae</i>	<i>Chenopodiaceae</i>	<i>Laminaceae</i>	<i>Polygonaceae</i>
<i>Caryophyllaceae</i>		<i>Ranunculaceae</i>	<i>Brassicaceae</i>

lagurus), Brandt's and Mandarin Voles (*Lasiopodomys brandti*, *L. mandarinus*), and Pikas (*Ochotona pusilla*, *O. pallasi*, *O. daurica* and few more species in montane steppes). Another and even more specific guild of grasslands burrowing mammals are totally underground rodents what in Russia includes several species of Blind Mole Rats (*Spalax microphthalmus*, *S. giganteus*), Zokors (*Myospalax altaicus*, *M. aspalax*, *M. psilurus*), and the most widespread in steppes the Northern Mole Vole (*Ellobius talpinus*). Burrowing, grazing, and food storing of these mammals are crucially important for forming grasslands soil and vegetation structure, removing primary production, and constructing micro-habitats for many invertebrates and even vertebrates. These mammals also are specifically important for functioning food webs in grassland and shrubland ecosystems.

Formerly the diversity of Russia's grassland mammals used to be much richer. For a long time after glaciations, the steppes and meadows of the temperate zone preserved remnants of the Late Pleistocene mammoth fauna: Mammoth, Bison, Musk Oxen, Saiga, Reindeer, Asiatic Lion, Cheetah, and others. The last typical inhabitants of the grasslands of the steppe and forest biomes of Eurasia—Aurochs *Bos primigenius*, Tarpan *Equus ferus ferus* and Przewalski's Horse (*E. f. przewalskii*) and Onager *Equus hemionus*—became extinct as late as the 17–19th century. A program on the restoration of the semi-wild population of Przewalski's Horse is being implemented since 2015 in the Orenburg Nature Reserve. The horses were brought from France and Hungary. In July 2018, the first foal was born in the Reintroduction Center and now, in 2019, 40 horses lived in the reserve on the grassland area of 165 km². The next group of the horses will be brought from the Minnesota Zoo.

Other mammal orders also have some specific representatives in Russian grasslands and shrublands, such as the Steppe Fox *Vulpes corsac*, Steppe Polecat *Mustela eversmanii*, Marbled Polecat *Vormela peregusna*, Steppe Cat *Felis lybica ornata*, and the Pallas's Cat *Otocolobus manul* among carnivores, and Long-Eared Hedgehog *Hemiechinus auritus* among Eulipotyphla, and *Lepus tolai* among Lagomorpha. Nevertheless most of these species in Russia are not numerous and/or have limited distribution near the boundaries of their ranges. Numerically dominating and widespread mammals in the Russian grasslands and shrublands are the common Palaearctic and Holarctic species like *Vulpes vulpes*, *Canis lupus*, *Mustela nivalis*, *M. ermynea* among carnivores, *Erinaceus romanicus*, *Sorex* spp., and *Crocidura suaveolens* among insectivores (Eulipotyphla), *Lepus europeus*, *L. timidus* among lagomorphs, etc.

Russian grasslands and shrublands serve as specific open habitats for many birds. Probably the most characteristic insectivorous and granivorous songbirds in the Russian steppe and meadow habitats are several species of Larks (*Alauda arvensis*, *Alauda leucoptera* [formerly *Melanocorypha leucoptera*], *Melanocorypha yeltoniensis*, *M. calandra*, *M. mongolica*, *Eremophila alpestris*, and some others), Wheatears (*Oenanthe oenanthe*, *O. pleschanka*, *O. isabellina*), Buntings (*Emberiza hortulana*, *E. calandra*, *E. citronella*, *E. cia*, *E. cioides* and some others) and several others. Typical for steppe grasslands are large ground-nesting birds, like Demoiselle Crane (*Grus virgo*), Little Bustard (*Tetrax tetrax*), and Great Bustard (*Otis tarda*; this species faces risk of extinction in Russia). A very characteristic and ecologically important bird guild in open habitats is raiding raptors hunting ground-dwelling small mammals, reptiles, birds, and

large arthropods. The guild includes Steppe Eagle (*Aquila nipalensis*), Imperial Eagle (*A. heliaca*), Buzzards (*Buteo rufinus*, *B. hemilasius*), Harriers (*Circus cyaneus*, *C. pygargus*, *C. macrourus*, and *C. spilonotus*), large and small Falcons (*Falco cherrug*, *F. tinnunculus*, *F. naumanni*) and some others. Most of the raptors are nesting on the ground but a few of them need trees or bushes for building nest. Another characteristic ecological group is birds of steppe wetlands which include many species of Waders, Pelecan, Herons, Grebes, and few very specific ducks (*Tadorna ferruginea*, *T. tadorna*, *Oxyura leucocephala*). Shelducks (*Tadorna* spp.) nest in the mammal burrows far away from water bodies.

Reptiles are not divers and numerous in Russian grasslands and shrublands in general but occur in several local regions (such as Caucasus foothills, Lower Volga, and Far East meadows). Characteristic for the entire Russia's grasslands are only few species of snakes and lizards: *Lacerta agilis*, *Eremias velox*, *E. arguta*, *Coronella austriaca* (west of Urals only), *Elaphe dione*, *Vipera renardii*, *Gloydius halys*. Meanwhile, grasslands and shrublands of some southern regions of Russia comprise up to 15–20 species of reptiles, including many Turanian and Mediterranean taxa (including representatives of *Gekkonidae*, *Agamidae*, *Scincidae*, *Boidae*, *Testudinidae*, and some other families which are absent from most of the Russian territory).

In general, the highest biogeographic units (as Mediterranean, Caucasian, Siberian, Far Eastern, Beringian, and others) differ in the distribution and composition of temperate grassland and shrubland communities. While the Ural Range is of no significance in this respect, the wide valley of the Yenisei River is an important boundary both for many of the inhabitants of open spaces and for their communities. In fact, the western meadow class *Molinio-Arrhenatheretea* is replaced here by the eastern class *Calamagrostietea langsfordii* (see [Appendix 1](#)). Also, the boundary between western steppes of the *Festuco-Brometea* vs. the eastern steppes of the *Cleistogenetea squarrosae* (see [Appendix 1](#)) runs here. The steppe fauna demonstrates effects of species vicariance from west to east. A good example is the sequence of the *Sciuridae* rodents: *Marmota bobak*—*M. baibacina*—*M. sibirica* and *Spermophilus suslicus*—*S. pygmaeus*—*S. erythrogenys*—*S. dauricus* replacing one another from the western edge of the Russian steppe belt to the eastern one.

Natural and Anthropogenic Communities (Including the Origin of Meadows)

The areas of *secondary grasslands* ([Fig. 1](#)) and *shrublands* ([Fig. 3](#)) of the forest zone are included in the summation of forest cover area. The forest cover of Russia's territory totals 45.4% (7,962,000 km²). Deforestation due to clearcuts and wild fires, which significantly increased in the 20th and 21st centuries, is a great challenge for Russia. Over the last decades, also a neutralizing process has been observed, namely abandonment of farming lands with further spontaneous afforestation. As a result, the forest area in Russia over the past decades only slightly decreased, by 5000–6000 km² nationwide.

Natural grasslands in Russia include zonal and extra-zonal steppes ([Fig. 2](#)), floodplain meadows along rivers and around lakes ([Fig. 1](#)), specific grasslands (meadows) of alase habitats (in thermokarst depressions of Yakutia), halophytic communities of continental and coastal salt marshes and other saline habitats. The genesis of natural grasslands of Russia is determined by the presence of specific conditions of climate, ecotopes, and soils, able to prevent the formation of tree canopy for a long time. For zonal *steppes*, for example, of importance is the value of the aridity coefficient, the ratio of precipitation (mm) to evapotranspiration or potential evaporation (the amount of moisture evaporated in a given climate from water surface), which is 0.6–0.9 in meadow steppe and >0.6 in typical and dry steppes (up to 0.1–0.3 is characteristic for deserts). Steppe grasslands on loess loams and clays form chernozems, dark soils containing a high percentage of humus, wash-resistant even under strong precipitations. Chernozem is one of the most fertile soils in the world. The northeast of Siberia is represented by cryo-arid relict (Pleistocene) steppes ("mammoth steppes"), and the slopes of thermokarst depressions (alases), by meadow steppe communities with *Calamagrostis neglecta*, *Hordeum brevisubulatum*, *Stipa krylovii*, *Festuca lenensis*, *Carex pediformis* and so on.

Floodplain meadows ([Fig. 1](#)) are natural intrazonal ecosystems that form on the flooded (for 15–45 days) part of river or lake floodplains on alluvial soils, annually enriched with silt. They are interspersed among any zonal biome in temperate climate. Among usual species, there are grasses, such as *Glyceria fluitans*, *Festuca pratensis*, *Elymus repens* (= *Elytrigia repens*), *Poa pratensis*, *Bromus inermis*, *Calamagrostis epigeios*, and others, as well as several species of *Carex*. Abundances of the specific dominating species depend on the dates and duration of the floodwater overflow.

The runoff of most large and middle-sized rivers of Russia's temperate belt, especially in the European part, is regulated by levees and dams of hydroelectric power plants. As a result, significant areas of floodplain communities, including meadows, have disappeared or changed, becoming dependent on the anthropogenic regime of dams' operation. A bright example is the Volga basin, where, as a result of runoff regulation, reservoir construction, deforestation, and continuous plowing of watersheds, about 30% of watercourses and large areas of floodplain meadows have disappeared over the last millennium. The river itself has turned into a cascade of nine large shallow reservoirs. One of them, the Rybinsk Reservoir (about 4580 km²) flooded floodplain meadows and willow thickets along the Volga itself on a distance of 110 km; along the Mologa River, 226 km; and along the Sheksna River, 328 km. Before 1940, this was one of the Europe's largest ranges of floodplain hay meadows, which supplied hay to a significant part of Russia's cavalry.

In the plains of Russia's temperate zone there are also some natural shrubland communities: in the forest biome, these are *erniks* in Siberia and the Far East with *Betula nana* (incl. subsp. *rotundifolia*), *B. fruticosa*, *B. exilis*, and *B. divaricata* (incl. subsp. *middendorffii*) and, less frequently, with *Salix* spp., *Rosa* spp., *Potentilla* (= *Pentaphylloides*) *fruticosa*, and *Alnus alnobetula* subsp. *fruticosa* (= *Duschekia fruticosa*); in floodplains, willow (*Salix* spp.) thickets; and in the steppe biome, thickets of *Genista tinctoria*, *Chamaecytisus ruthenicus*, *Caragana frutex* and other *Caragana* spp., *Prunus stepposa*, *Prunus tenella* (= *Amygdalus nana*), *Prunus* (= *Cerasus*) *fruticosa*, *Rhamnus cathartica*, *Crataegus* spp., *Rosa* spp., *Tamarix meyeri*, *T. ramosissima* and other shrubs.

The grasslands of the forest biome's plain watersheds (meadows and weed brushes) are exclusively of anthropogenic origin. They represent early stages of the progressive succession, which form after (1) logging, (2) drainage of bogs, (3) forest fires, (4) abandonment of farmlands, and so on. The main condition of their long-standing existence without trends toward afforestation and changes in the structure, flora composition, and productivity is intentional or spontaneous human control over their dynamics. The succession may be blocked, which excludes the start of the forest stage, due to annual or periodic mowing, continuous grazing by livestock, and periodic burns (in spring or fall) with a frequency excluding the formation of a forest cover. Upland post-forest meadows in many regions of the East European Plain are results of millennia-long evolution of the temperate agricultural landscape. They are relatively stable subclimax communities with a "conservative" flora composition, a soil seed pool corresponding to the actual flora composition, and other mechanisms to exclude alien species invasion.

Similar properties are typical for secondary (anthropogenic) steppes, which formed on set-asides after long-standing plowing, on degraded steppe pastures, and on eroded lands. With the area of the steppe zone of about 1,370,000 km² (8.0% of the Russia's territory), preserved parts of the steppes and natural steppe and shrubland communities proper are represented in European Russia (Belgorod, Voronezh, Kursk, Saratov, and other provinces) on 3%–15% of the region's area and in Siberia (Buryatia, Altai, Tyva, Novosibirsk oblast, Transbaikalia, etc.), on 30%–50% (Map 2). The exceptions are Kalmykia where desert steppes occupy about 50,000 km², Orenburg oblast with 20,000 km² (including two large blocks of over 1000 km²), Tyva with 27,000 km², and Transbaikalia with almost 20,000 km². The most disastrous situation with plowing and degradation of steppe vegetation occurs in the provinces of Voronezh, Kursk, and Belgorod, where fragments of secondary steppes are preserved on 1.0%, 1.3%, and 1.7% of the region's area, respectively (Map 3). Overall, following the results of the implementation of the UNDP/GEF (United Nations Development Programme/Global Environmental Finance) project of 2010–2016 "Improving the Coverage and Management Efficiency of Protected Areas in the Steppe Biome of Russia," 10,178 tracts of steppes were identified in the 29 provinces of Russia (Table 4). Their area totaling 179,700 km² and the average area of an individual steppe tract is 17.65 km² (Rogova and Skvortsov, 2016).

The Classification of Grasslands and Shrublands of Russia

The problems of the typology of grasslands and shrublands on the plains of Russia's forest and steppe biomes are associated, on the one hand, with the anthropogenic origin of many of them and, on the other, with their combination with upland and floodplain

Map 3 The actually existing steppe sites in Belgorod oblast, identified by the 2011–2016 inventory (<http://savesteppe.org/ru/maps>).

Table 4 Areas of the actually existing plain steppes in some provinces of Russia.

Province (oblast, krai, republic)	Area of the province (km ²)	Number of identified steppe sites	Area of steppe (km ²)	Share of the area of the region (%)
Astrakhan	58,265	163	14,765	25.3
Belgorod	27,151	702	471	1.7
Chelyabinsk	88,637	245	4510	5.1
Kalmykia	72,105	196	48,377	67.1
Kursk	30,002	1088	388	1.3
Lipetsk	24,066	1079	449	1.9
Novosibirsk	177,850	84	2246	1.3
Omsk	141,256	23	936	0.7
Orel	24,648	290	427	1.7
Orenburg	124,305	2437	22,869	18.4
Penza	43,394	254	321	0.7
Rostov	102,838	1202	8092	7.9
Samara	53,881	895	1649	3.1
Saratov	101,182	2502	5993	5.9
Stavropol	66,178	443	5889	8.9
Tambov	34,456	1296	1305	3.8
Tatarstan	68,013	383	348	0.5
Transbaikal	432,070	278	17,159	4
Ul'yansk	37,227	254	459	1.2
Volgograd	112,871	2612	16,814	14.9
Voronezh	52,248	257	522	1

Based on inventory by remote sensing data with further field verification 2011–2016.

woodlands, wetlands, halophytic vegetation, and so on. Shrub layer also affects the composition and classification status of steppe herbaceous communities. In other cases, the shrubs form shrublands which would be classified as a specific type, not a variant of grassland. The classification on dominants might introduce corrections and could allow a more deterministic classification of these plain communities within the forest and steppe biomes. However, the dynamic character of their composition (owing to successional variation and the temporary existence of grasslands and shrublands themselves) does not allow a correct use of approaches and methods other than floristic classification. The background and bibliography of the Braun-Blanquet approach, used to classify vegetation, including grasslands and shrublands, in Russia and neighboring countries, were presented in [Solomestch et al. \(1994\)](#) and [Mirkin and Ermakov \(2010\)](#).

To reflect higher units of the classification of grasslands and shrublands of Russia's plains, we used the prodromus prepared by [Ermakov \(2012\)](#). For temperate grasslands, it includes 18 classes, 35 orders, and 92 alliances; for steppe shrubland communities, four classes, five orders and eight alliances ([Appendix 1](#)).

Of special interest is the typology of plain variants of dwarf birch, willow, and *Duschekia fruticosa* communities in Siberia and the Far East. Most of them within the forest zone form primary and secondary thickets (*ermiks*). A similar situation is observed with *Pinus pumila* communities, which form at the foothills and on the plains of Siberia and the Far East, including on Kamchatka's coastal plains, which are included in the class of boreal forests Vaccinio-Piceetea. No doubt, in terms of spread and the organization of the communities themselves, they are thickets of large shrubs, which, in the boreal conditions of the northern taiga and continental *Larix* spp. woodlands, extend to the plains. This allowed Ermakov and colleagues ([Ermakov et al., 2002](#)) to attribute the alliance *Vaccinio-Pinion pumilae* to the class *Loiseleurio-Vaccinietea* of shrub heathlands, which can also form on plains in temperate climate.

Ecology and Biodiversity

Ecologically, temperate grasslands and shrublands of Russia's plains are mesophytic, xeromesophytic, and mesoxerophytic communities. Absence of tree cover affects all aspects of their ecology. First, these are communities of heliophilous plants and animals, which prefer open spaces and can find refuge within the herbaceous or shrub horizon (within a range of 0.5–2.5 m). Second, the leading role in their functioning and dynamics is played by small burrowing mammals and, overall, soil fauna. They ensure active soil-building processes, a deeper rainfall penetration, the development of the biogenic microrelief, and the spatial mosaic of the communities. Third, these are ecosystems with domination of grazing-based food web (not detritus-based ones), i.e., functionally oriented at the active consumption of phytomass in the annual cycle and the exclusion of excessive litter accumulation.

By climatic parameters (attitude to heat), these ecosystems have a unique, exceptionally wide range: by average annual temperature, from −15.0 to +12.0 °C; by average July temperature, from +7.0 to +25.0 °C; by average January temperature, from +0.0 to −42.0 °C; and by annual precipitation, from 250 (in the Caspian steppes) to 1100 mm in Kamchatka's valleys. The reaction norm of these ecosystems is one of the widest and occupies wide "portions" of physical gradients of life, "within" climatic ranges of zonal biomes, which testifies to their anthropogenic genesis and existence as a forestless subclimax: pyrogenic, pascual, agrogenic, and

floodplain. A part of the range of the ecosystems under consideration is developed in continental climate conditions. For example, in Yakutia with its extensive representation of meadows, alases, cold steppes, and shrublands, the difference between the maximal (+38.4 °C) and minimal (−64.4 °C) temperatures is more than 100 °C.

An important ecological factor for the grasslands and shrublands of Russia's temperate belt is their formation on permafrost, where the active layer can vary from 20–30 cm to 1.5–2.0 m. However, typical of floodplain meadows and shrublands are floodplain and lake taliks and of marshes, submarine taliks. Within the forest zone in Siberia, widespread are anthropogenic taliks with secondary meadow vegetation on frozen grounds.

The soil pH, content of Cl, Na, and Ca ions in soils vary widely under Russia's grasslands and shrublands. Meadows, marshes, and steppes represent the entire spectrum of halophilous and calciphilous ecosystems, including such extremely calciphilous ones as steppes on chalk deposits and limestone outcrops. Examples of widespread of halophilous grasslands and shrublands can be found in the Caspian Depression and in Southern Urals where halophilous communities are represented by following syntaxonomical classes (*Festuco-Puccinellietea*; *Scorzonero-Juncetea gerardii*; *Nerio-Tamaricetea*) (see [Appendix 1](#)).

The ecological features of grasslands and shrublands also include their biological and economic productivity ([Titlyanova et al., 2018](#)). The productional potential of their seasonal use as natural forage lands (hay fields and pastures) is sufficiently high. Biological productivity in zonal (steppes) and intrazonal (floodplain meadows) grasslands vary widely ([Table 5](#); [Tishkov, 2005a](#); [Titlyanova et al., 2018](#); [Bazilevich et al., 1986](#); [Tsarevskaya, 1989](#)). [Table 5](#) does not present numerous assessments for meadows and shrublands of the Far East, the Kamchatka Peninsula, Sakhalin, and the Kuril Islands with *Filipendula camchatica*, *Angelica ursina*, *Reynoutria sachalinensis*, *Petasites amplus*, *Sasa kurilensis*, where extremely high figures of both total phytomass (up to 57–90 t ha^{−1}) and net primary production (35–57 t ha^{−1} year^{−1}) are recorded.

The annual primary production in upland post-forest meadows is close to those of the zonal forests on the same territory. However, the proportion of above-ground and below-ground phytomass depends on the position in the relief and the slope exposure, i.e., on water supply, arriving heat, and the conditions of the transit and accumulation of nutrients ([Table 6](#)). Studies on the productivity of meadows in the Valdai National Park (southern taiga of European Russia) have shown that the both total phytomass and net primary production increase top-down along the slope ([Table 6](#)).

Plain grasslands are the economically most important biome of Russia. They serve as a natural base for both arable farming and animal husbandry. For example, the steppe zone yields over 85% of the total Russian grain harvest, feed over 70% of cattle, and produce over 90% of sheep and goat wool. Their ecosystem services, including long-term and reliable carbon depositing, are critically important for human life and the economy. The preserved natural grasslands provide for the survival of globally endangered and vulnerable species of mammals and birds and, at the national level, for more than 100 rare species of plants and animals ([Smelansky and Tishkov, 2012](#)).

Ecosystem services of grasslands can be assessed in both physical and monetary values ([Table 7](#)). Carbon storage is a significant part of their total value. For example, the total carbon storage in steppe soils of Russia's plains is estimated at more than 100 million tons in the uppermost 1 m of depth (under the total area of the zone: 2232 km²). This is about 25% of the total carbon storage deposited in Russia's soils and it is held in the soils occupying only about 13.5% of the country's area ([Smelansky and Tishkov, 2012](#); [Romanovskaya et al., 2019](#)). Generalized assessments of ecosystem services of grasslands and shrublands are presented in the national report on ecosystem services of Russia ([Bobylyev et al., 2018](#)).

The total area of actually existing steppe ecosystems in Russia is estimated at about 500,000 km² ([Smelansky and Tishkov, 2012](#)). Assuming the above-mentioned evaluation of the total amount of carbon, its total stock for Russia's steppe biome can be estimated at 35 billion tons. The total long-term average annual potential of carbon deposition in steppe ecosystems is estimated at 75 million tons per year.

In the soil of protected meadow steppe on the East European Plain (Kursk Province) the amount of bound organic carbon is estimated at 462 t ha^{−1} (at a soil depth of 2 m) ([Table 7](#)). On the neighboring annually mowed steppe plot the carbon storage is a bit smaller, 451 t ha^{−1} ([Mikhailova and Post, 2006](#)). For the soils of meadow steppes, the share of carbonates is estimated at about 30%. Therefore, the total carbon storage in the chernozem underlying unused meadow steppe is about 700 t ha^{−1}, only 3.5% of which has a turnover period of about 300 years, while for the rest of the pool this period is estimated at thousands

Table 5 The average phytomass and production of the grasslands and shrublands in Russia.

Zonal and azonal ecosystem	Phytomass (t ha ^{−1})	Litter (t ha ^{−1})	Net primary production (t ha ^{−1} year ^{−1})
Floodplain meadows	6.0–55.0	1.0–5.0	5.0–45.0
Meadow steppes	15.0–30.0	10.0–20.0	18.0–25.0
Steppes	10.0–30.0	10.0–15.0	15.0–20.0
Dry steppes	8.0–15.0	8.0–12.0	6.0–15.0
Desert steppes	5.0–10.0	10.0–12.0	4.0–8.0
Shrublands of the forest and steppe zones	25.0–60.0	3.0–6.0	10.0–15.0

Table 7 Volumes and estimated monetary values of some groups of ecosystem services in the meadow steppe of Central Chernozem Zapovednik (Nature Reserve), Kursk Province.

Some groups of ecosystem services	Central Black Earth Nature Reserve	
	Absolute values for calculation	Estimated monetary value ($USD\ ha^{-1}\ year^{-1}$)
Climate-regulating services (including carbon depositing)	Humus content in the upper 10 cm of the soil is 9%–12%, while the stock in the 2 m depth layer is 540 t/ha. Carbon sink can be 1.5–2.5 t/ha per year	75–125
Water-regulating services (runoff provision and decreasing water losses; calculation through compensation)	Compensation (substitution) is calculated through possible costs of the runoff-regulating “activity” of oak forests and steppes	30–50
Assimilative services (neutralization of pollutants and excessive biogens; calculation through compensation)	Assimilative properties of chernozems	10–15
Soil protection services (erosion risk decrease, through costs of eroded land restoration)	Amount to 2.0–4.0% of restoration costs at a steppe secondary succession rate of 40–60 years	20–40
Production and biological resource services (costing hay yield; value of wild berries, mushrooms, medical and aromatic plants, and wildlife, including the function of its reproduction for neighboring areas)	Hay yield is up to 0.4–0.6 t/ha (at about \$50 per ton); primary production in steppe pasture is up to 1.5–2.0 t/ha of herbage per grazing season (at a carrying capacity of 0.3–0.5 head per hectare); and honey yield, 20–80 kg/ha per season	40–120
Information services	Unique biodiversity, monitoring of biota, a museum, a visiting center, a weather station. Assessed through the costs of inventory, natural object mapping, scientific studies, and arrangements for ecological monitoring	25–50
Recreational services (use for tourism and ecological education)	The reserve is annually visited by about 4000 persons (primarily excursions by ecological routes and visits to the museum)	5–10
Total		200–410

Data from Estimates and calculations of A. Tishkov specifically for this review.

of years. Hence, in terms of carbon “binding” effectiveness and global climate regulation, the role of Russia’s grasslands is comparable with that of boreal forests (taiga).

According to Costanza et al. (1998), the specific value of grasslands is about $232\ USD\ ha^{-1}\ year^{-1}$ and their global estimated monetary value reaches 906 billion USD per year (higher than that of boreal and temperate forests). What is the share of Russia’s grasslands in the figure? We estimate it at about 12% of the volume of potential ecosystem services of the global grassland biomes. In addition to the unique role of chernozems as carbon stock and its influence on the greenhouse gas concentration in the atmosphere, the following aspects can be specifically important (Tishkov, 2005a,b): (1) river runoff regulation (for example, the restoration of steppe vegetation in the region increases the river runoff by up to 10.0%), (2) grassland radiation balance is 20–30% higher than that of barren soil, and (3) the substitution of primary steppe vegetation by its anthropogenic modifications changes albedo by 3–9%.

Threats

Threats to floodplain meadows and shrublands of Russia are largely associated with plain river runoff regulation and dam construction. Many floodplain areas have been flooded with shallow waters of the reservoirs (constituting 20–70% of the aquatic area), while meadows and shrublands downstream of the dams dry and transform because of the lack of normal floods. The threat of fires is lower here, although it is annual burns that have become a real threat, for example, for the grasslands of the Amur River basin.

The threat of invasive alien plant species has become characteristic of the last decades. The Black Book of European Russia (Vinogradova et al., 2010) among the 100 most aggressive invasive species identifies many ones usual for floodplains, such as *Echinocystis lobata*, *Heracleum sosnowskyi*, *Acer negundo*, *Bidens frondosa*, *Impatiens parviflora*, *Hippophaë rhamnoides*, *Phragmites altissimus*, *Zizania latifolia*, and others.

The current threats to upland meadows of the forest zone are associated with the following processes: (1) decrease of traditional farming and drop in the livestock number what lead to dramatic decrease of mowing and grazing areas; (2) amelioration, which can include changes in the drainage, leveling, boulder clearance, weed control, fertilization, forage herb seeding, and so on; (3) local over-grazing in and around large farms and villages; (4) increase of burns which kill a part of the land biota and form weed brushes in places of complex invasion-resistant meadows; and (5) alien species invasions.

Main threats to natural steppes follow from the agricultural value of steppe soils. Historically turning grasslands into arable was the worst threat for steppes in Russia (Chibilev, 1998; Moon, 2013; Smelansky and Tishkov, 2012). The total steppe area turned into arable land is assessed at almost 1,000,000 km² nationwide (for 1990, the peak value). Meadow steppes and typical steppes in European Russia (west of Volga R.) have disappeared on almost 95% of their area. The collapse of the USSR has resulted in massive cropland abandonment followed by spontaneous restoration of grasslands and then partial re-plowing 15–20 years later (Prishchepov et al., 2012; Schierhorn et al., 2013; Alcantara et al., 2013; Reinecke et al., 2018).

Actual threats were analyzed under framework of the UNDP/GEF project “Improving the Coverage and Management Efficiency of Protected Areas in the Steppe Biome of Russia” (2010–2016). The primary threat is still a direct destruction of natural and semi-natural steppes by plowing for permanent crops (not only for food production but also for forage and biofuel). Conversion into cropland is specifically dangerous for secondary steppes nationwide and for meadow steppes and typical steppes of European Russia where natural steppe sites are in peril.

Destruction of steppe grasslands by mining, oil and gas industries is now the next most important threat. The oil and gas industry is an important driver of fragmentation, degradation, and pollution of steppes in Volga-Urals region while mining is specifically important in South Urals, Altai, Khakassia, and Transbaikalia.

Overgrazing and undergrazing both threaten Russian steppes. The livestock number in Russia decreased dramatically after 1990. During the decade 1990–2000 the cattle number had dropped to half of the 1990 figure, and sheep and goats' number did to a third of the 1990 level. Currently overgrazing is an important threat for dry and deserted steppes of the Caspian and Caucasus regions (specifically Dagestan, Kalmykia, and Stavropol) and steppes of Altai and Tuva (Fig. 4) where livestock numbers are high and continue to rise (Smelansky and Tishkov, 2012; Reinecke et al., 2018). At the same time, undergrazing is especially important in the meadow steppes and typical steppes of European Russia and several provinces of Southern Siberia, driving deterioration of grasslands, spontaneous afforestation, and disappearance of many specific grassland species (Reinecke et al., 2018).

Undergrazing also is important as a driver causing a rise of steppe fires. Wild fires that became numerous and frequent after 2000 are an important threat for steppe grasslands and shrublands causing deterioration of habitats and direct destruction of some steppe species (Smelansky, 2015). Currently wild steppe fires have a huge spatial extent in Russia but their ecosystem effects are contradictory (Fig. 4). Steppe fires are specifically extensive and frequent in Pre-Caucasian, Volga-Urals, West Siberia, Khakassia, and Transbaikalia regions.

Fragmentation with infrastructure (roads, pipelines) is a threat to small steppe sites, specifically in European Russia. Afforestation projects are potentially dangerous but have little extent and are generally rare in Russia. Encroaching of weeds and invasive plant species is a threat attracting special attention in recent years.

Conservation, Restoration, and Sustainable Management

A big problem for Russia's steppes is an absence of any clear governmental policy regarding their use and conservation. The Russian legislation does not distinguish steppes as a specific object of regulation and conservation management. Meanwhile, several types of steppes are currently considered among the most imperiled ecosystems in Russia (Smelansky and Tishkov, 2012). The main conservation instrument for protecting steppes in Russia is federal and provincial systems of protected areas (PAs). As assessed by the end of 20th century, only 0.11% of the area of steppe biome in Russia was formally covered with federal protected areas (PAs). Such assessment for provincial PAs at that time could not be made due to lack of available information (Smelansky and Tishkov, 2012). During the last two decades the area of steppe ecosystems under protection and number of PAs protecting steppes increased tenfold and even more at both federal and provincial levels. Also information on provincial PAs became available for assessment. In 2018 the area of steppe ecosystems under protection in Russia reached 2.4–2.5 million hectares and makes a solid figure of 4.3–7.7% of the national area of the steppe biome (depending which assessment of the biome area we use). This protected steppe area is divided almost equally into federal and provincial PA systems. Steppe grasslands and shrublands are conserved in about 600 sites within about 550 PAs (including 84 sites of 51 PAs belonging to federal level). Meanwhile, the steppe biome is still among

Fig. 4 Turning grassland into arable: (A) just re-plowed secondary steppe, Altai Territory. Photo by I. Smelansky; (B) just re-plowed secondary steppe, Samara Province. Photo by I. Smelansky. Grazing in natural pastures of Russia: (C) grazing in dry steppe, Altai Republic. Photo by I. Smelansky; (D) winter grazing in overgrazed dry steppe, Khakass Republic. Photo by I. Smelansky. Wildfires in grasslands of Russia: (E) spring fire in the typical steppe, Orenburg Province. Photo by I. Smelansky; (F) just burnt typical steppe with *Caragana microphylla* shrubs, summer fire, Transbaikalia Territory. Photo by I. Smelansky; (G) post-forest meadow, Primorsky Territory. Photo by K. Kobayakov; (H) "pyrogenic savanna," Territory Primorsky kray. Photo by K. Kobayakov.

the least protected in Russia and needs more protection (Smelansky and Titova, 2018). In total, temperate grasslands comprise not more than 2% of the total area of the federal PA system. Also, often the PAs provide steppes with only formal protection as their regimes are not optimal for long-term conservation of grasslands.

Conservation of floodplain meadows and shrublands is also important since they are both forage lands and valuable ecotopes of floodplain fauna, including wetlands, because plain river runoff regulation has changed the flooding schedule of floodplains. Many floodplains found themselves under reservoirs' water, and their extents lying downstream of dams stopped functioning as floodplain ecosystems and partially lost their typical biota. Floodplain grasslands and shrublands are conserved only in the Khopersky, Volga-Kama, and Oksky nature reserves; in the Nyzhne-Kamsky and Ugra national parks; and in the Volg-Akhtubinsky "floodplain" Nature Park.

In the context of the large-scale cutback in agricultural production in Russia's forest zone, the recently formed pool of set-asides and abandoned hay meadows and pastures (according to different estimates, up to 300,000 km²) is gradually becoming covered with small-leaved forests (*Betula* spp., *Alnus incana*, *Populus tremula*, *Salix* spp.) and, on sandy soils, with pine forests (*Pinus sylvestris*). The conservation of, for example, the ancient Russian forest-field-meadow landscape in European Russia, in which the share of upland meadows reached 20–30% of its area, requires supporting by traditional agricultural production oriented at dairy husbandry, implying hay making and seasonal grazing. This problem is especially acute for the networks of protected areas of the forest and meadow-steppe zones, where the introduction of the conservation regime often has resulted in the afforestation of meadows and steppes.

In recent years, Russia has encountered a relatively new problem, the conservation of forest zone grasslands. For the numerous waterfowl birds of the Arctic (geese, cranes, sandpipers), grasslands in the agricultural landscape are the key territories of concentration and rest during migrations. The GPS-GSM-supported Russian-German studies on the migration of geese within the international ICARUS program (Wikelski and Terbitski, 2016) show that changes in the structure of agricultural lands, the decrease in the livestock, the reduction of the tillage area, and the foresting of meadows and set-asides have shifted the birds' migration routes from the center of the East European Plain toward the Baltic Sea coast.

For saving the most destroyed ecosystems, meadow steppes and dry meadows of European Russia, conservative methods probably are not sufficient, they need restoration. The restoration measures include active and passive methods. Active methods using seeds from natural vegetation locations were developed for various regions of the Old World (Dudar, 2000; Dzybov, 2010; Tishkov, 2000). The main limiting factor here is an absence of special seed nurseries, "wildflower farms." To create stable seeded meadow or meadow steppe with a balanced species composition and high productivity, the Fodder Institute developed new technologies (Trofimova and Kulakov, 2012; Kosolapov and Trofimov, 2014). An important element of these technologies is their adaptation to various climatic, soil, and landscape conditions and testing within long-standing experiments at the zonal stations of the Fodder Institute of Russian Academy of Sciences.

Passive methods of grassland restoration include protection against burns, a decrease in pasture loads, temporary isolation of large ranges from grazing, and the creation of protected areas on degraded lands for the development of a progressive succession.

Anyway, the overwhelming majority of the Russian grasslands area cannot be covered with protected areas and will stay as productive landscape. Obviously these grasslands should be saved by management methods.

Management to maintain the stability of Russia's grasslands includes (1) choosing optimal technologies, loads, periodicity, and grazing seasonality; (2) choosing a mowing regime optimal in terms of time, frequency, and the use of technical means; (3) conserving the biodiversity and forming regional networks of protected grassland localities with different management regimes; (4) preventing and combating grass fires and agricultural burns; (5) the ecological restoration of eroded and disused agricultural lands; (6) measures on fertilization and amelioration of ecosystems used in farming; and (7) strategic actions aimed at the reproduction and reintroduction of animal species important for the functioning of grasslands.

Management in agricultural use is a powerful driver of the conservation and maintenance of the sustainability of ecosystems, both meadows and steppes. Under the influence of grazing and mowing (for floodplain meadows, of seasonal floods as well), there formed stable, long-term ecosystems, diverse in composition and productivity.

As was shown above, on the forest zone plains the grasslands used for agriculture occupy 250,000 km². Their average economic yield (in dry weight) is 1.0–1.1 t ha⁻¹ (on watersheds) and 2.0–2.5 t ha⁻¹ in the floodplain. The forage reserve on natural forage lands of the forest zone is 25–35 million tons. In the forest-steppe and forest zones, controlled grasslands occupy 340,000 km². Due to the high plowing (50%–75%), inarable (slope) lands are used for grazing. Hay fields are primarily in floodplains and lowlands. The average economic yield on a watershed is 0.7–0.8 t ha⁻¹ and in a floodplain, two to three times higher. The forage reserve on natural forage lands of the forest-steppe and steppe zones is 20–25 million tons. In dry and desert steppes of Russia, there are 93,000 km² of herbal pastures with an average yield of 0.25–0.35 t ha⁻¹ and a forage reserve of 2.0–4.0 million tons on dry basis.

Livestock usually spend 130–160 days on pastures in the forest zone; in the forest-steppe zone, 160–200 days; in meadow steppes and typical steppes, 180–200 days; and in dry steppes and desert steppes, 220–280 days. Pasture herbage and good hay have always been the cheapest and biologically most complete feed. Their share in animals' ration should not decrease. For their production, 200,000–250,000 km² of natural and seeded hay fields and pastures are annually mowed in Russia. The optimal management mode in using pastures and hay fields requires (1) shredding and mowing plants in a state that can ensure a maximal yield from the animals; (2) feeding a maximal number of animals; and (3) preserving the yields of pastures and hay fields and the forage composition of their plants at a high level during the entire period of use and, at the same time, creating conditions for a further increase in the yield. All this can be attained considering the needs of animals and the response of plants to the usage mode.

The management of the dynamics of grasslands involved in agricultural production, consists of the following elements: (1) establishing an optimal height, time, and frequency of the use of the herbs; (2) choosing methods of use during the pasture season and by years; (3) using grazing and mowing rotations; (4) equipping the pasture territory, making up a herd, and choosing a pasture-day order; and (5) daily pasture and hay-field farming.

The regime of using grasslands as pastures (Fig. 4) corresponds to the composition of herbage: in the forest zone, three to four shredding cycles per season; in steppes, five to seven cycles. On average, one conditional head requires from 1.2–1.5 to 2.5–3 ha of pastures (Kosolapov and Trofimov, 2014).

Control over grasslands in the agricultural sector, which conflicts with the tasks of biodiversity conservation, is associated with the introduction of low-cost technologies of simplified improvement and progressive succession stimulation up to the stage when it becomes possible to maintain and even increase the share of valuable forage species in the stand by regulating grazing and mowing. Another result of the introduction of this technology will be the creation of everlasting pasture and hayfield phytocoenoses.

The long-standing experience of the conservation of grasslands on the plains of Russia's temperate zone shows that prospects here are associated exclusively with the restoration of beef (steppes) and dairy and meat (meadows of forest zone) husbandry. They should occupy the leading place in the traditional agricultural landscape and fulfill not only feeding but also environment-forming, protective, and recreational functions. Strategically, natural grasslands and their anthropogenic modifications can become a buffer between urbanized territories and intensive agriculture, dairy farms, and tillage, relieving the latter from some of the loads related to forage growing. In combination with the development of a network of protected territories, the area of which, according to the Goals of Sustainable Development in Russia, must be no less than 17%, grasslands in the steppe zone should constitute the ecological framework of the country's temperate belt.

Appendix 1: Syntaxonomic Prodrum of the Meadows, Steppes and Shrublands of Russia (Largely Following Ermakov (2012)) (Presented in the Ecological Order: Meadows, Steppes, Communities of Forest Edges, Communities of Inland Continental Saline Territories)

Class Molinio-Arrhenatheretea TX. 1937 – Secondary post-forest meadows of the temperate zone of the Western Eurasia on fairly rich non-saline lands

Order Althaeetalia officinalis Golub & Mirkin in Golub 1995a – Meadows of steppe and deserted steppe zones of Southeast Europe on lightly saline and moderately saline soils of river valleys, which are flooded for a long time

All. Althaeion officinalis Golub & Mirkin in Golub 1995b – Meadows of the Middle Volga valley on slightly saline and moderately saline soils, flooded during the spring-summer floods for a long time

All. Euphorbion palustris Ageulov & Golub in Golub 1995c – meadows of the river Ural valley, flooded during spring floods for 1–1.5 months, on slightly saline and moderately saline soils

Order Arrhenatheretalia Pawlowski et al. 1928 – Mesophytic meadows on well-drained mineral soils. Temperate zone of the Western Eurasia

All. Festucion pratensis Sipailova et al. 1985a – Meadows on well-drained, relatively rich mineral soils in Eastern Europe and Western Siberia

All. Cynosurion cristati TX. 1947a – Low grass meadows of the forest zone of the European part of Russia with hay-pasture use on poor, slightly acidic soils

Order Carici macrourae-Crepidetalia sibiricae Ermakov, Maltzeva & Makunina 1999a – Natural and semi-natural post-forest meadows of the forest-steppe and south of the forest zone of Southern Siberia and the Southern Urals

All. Polygonion krascheninnikovi Kashapov 1985b – Mesophytic post-forest meadows of the Southern Urals

All. Crepidion sibiricae Mirkin ex Ermakov, Maltzeva & Makunina 1999b – Post-forest meadows of humid well-drained habitats of plains and mountains of Southern Siberia

All. Aconito barbati-Vicion unijugae Ermakov, Maltzeva & Makunina 1999c – Post-forest meadows of moderately humid and moderately dry habitats of plains and mountains of Southern Siberia

Order Galietalia veri Mirkin & Naumova 1986a – Steppe meadows of Eastern Europe and Western Siberia, forming in a continental climate

All. Trifolion montani Naumova 1986b – Steppe meadows of forest-steppe and steppe zones of Eastern Europe and Western Siberia

All. Artemision ponticae Golub & Savelyeva in Golub 1995d – Steppe meadows in the valley of the Lower Don river and its tributaries

All. Seselion libanotis Ageulov & Golub in Golub 1995e – Steppe meadows in the valley of the Lower Ural and its tributaries

All. Scabioso ochroleucae-Poion angustifoliae Bulokhov 2001a – Steppe upland meadows of the southern forest part of the forest zone (subzone of deciduous forests) and forest-steppe zones within the Central Russian Upland

All. Agrostion vinealis Sipailova et al. 1985c – Dry meadows on sandy soils in the floodplains of southeastern Europe, transitional to the class of pioneer vegetation

All. Trifolion lupinastri Mirkin in Tuzhilin 1988a – Mesoxerophytic meadows of the northern Baikal region (Central Siberia)

- All. *Vicio-Hemerocallion lilio-asphodeli* Mirkin in Alimbekova & Mirkin 1989a – Rich meadows of the floodplains of the Lena and Yenisei rivers (Central Siberia)
- Order *Molinietalia* Koch 1926a – Wet meadows on mineral soils, Eastern Europe and Western Siberia
- All. *Caltion palustris* Tx. 1937 – Wettest meadows of the order, Eastern Europe and Western Siberia
- All. *Deschampsion cespitosae* Horvatić 1930 – Wet meadows of rich mineral floodplain soils, Eastern Europe and Western Siberia
- All. *Lythro-Euphorbion* Mirkin & Naumova 1986c – Wet meadows on floodplain soils of variable moisture regime in the lower parts of the river valleys in the deserted steppe zone of the European part of Russia
- All. *Molinion caeruleae* Koch 1926b – Wet meadows on mineral and peaty soils, with signs of transition to swamps
- All. *Anemonidion dichotomae* Mirkin in Iljina et al. 1988b – Wet meadows of the river valleys of the Western Siberia
- All. *Alopecurion arundinacei* Kononov in Kononov et al. 1986d – Swampy meadows on permafrost and bog soils
- Order *Potentillo-Polygonetalia* Tx. 1947b – Temporarily flooded disturbed meadows:
- All. *Potentillion anserinae* Tx. 1947c – Wet meadows of pasture use with a predominance of undersized hygrophilous species
- All. *Puccinellio-Agrostion stoloniferae* Gogoleva et al. 1987a – Communities of waterlogged, trampled solonchek habitats of Eastern Siberia.
- Class *Calamagrostetia langsdorffii* Mirkin in Achtjamov et al. 1985d – Communities of swampy floodplain meadows, East Asia
- Order *Calamagrostietalia langsdorffii* Achtjamov et al. 1985e – Floodplain meadows of northeastern Asia
- All. *Calamagrostion langsdorffii* Achtjamov et al. 1985f – Reed floodplain meadows of northeast Asia
- All. *Caricion schmidtii* Achtjamov et al. 1985g – True and swampy meadows in conditions of strongly variable water regime
- Class *Arundinello anomalae-Agrostietea trinii* Ermakov & Krestov 2009a – Dry land stepped meadows and meadow steppes, East Asia.
- Order *Artemisietalia mandshuricae* Achtjamov et al. 1985h – Driest type of meadows of deciduous forest and forest-steppe zones of Southern Primorye, Amur Region and Eastern Transbaikalia
- All. *Arundinellion anomalae* Achtjamov et al. 1985i – Meadows of Southern Transbaikalia and Mongolia;
- All. *Polygono alopecuroidis-Anemonastrion criniti* Arbuzova 1990 – Steppe meadows of Southern Transbaikalia and Mongolia
- Order *Carici schmidtii-Agrostietalia trinii* Ermakov & Krestov 2009b prov. – communities of medium-humid real meadows, common both in watersheds and in river valleys
- All. *Agrostion trinii* Achtjamov et al. 1985j – communities of real watersheds and river valleys meadows under the conditions of a variable regime of atmospheric humidification of the monsoon climate
- Class *Festuco-Brometia* Br.-Bl. & Tx. ex Soo 1947d – Xerothermic and hemixerothermic steppes of the Western Palearctic
- Order *Brometalia erecti* Koch 1926c – Subatlantic and sub-Mediterranean semi-xerophytic grassland communities on plain, Kerch peninsula (Crimea)
- All. *Bromion erecti* W. Koch 1926d – Subatlantic and sub-Mediterranean semi-xerothermic grass communities dominated by *Bromus* species
- All. *Cirsio-Brachypodion pinnati* Hadač & Klika in Klika & Hadač 1944a – More xerothermic subcontinental herbal communities of the Central and Southeast Europe
- Order *Festucetalia valesiacae* Br.-Bl. & Tx. ex Br.-Bl. 1949 – Subcontinental and continental meadow steppes of Central, Eastern Europe and Western Siberia:
- All. *Festucion valesiacae* Klika 1931a – Subcontinental and continental meadow steppes of Eastern Europe and Western Siberia
- All. *Poo urssulensis-Artemision glaucae* Saitov & Mirkin 1991a – Xeromesophytic steppes of the Ob riverside in the south of Western Siberia
- All. *Amygdalion nanae* Golub in Iljina et al. 1991b – Continental shrub steppes of Eastern Europe and Siberia
- All. *Galatellion biflorae* Korolyuk 1993a – Steppe meadows on slightly saline solonchek chernozem-like soils of the steppe zone of Western Siberia
- Order *Stipetalia sibiricae* Arbuzova & Zhitlukhina ex Korolyuk & Makunina 2001b – Meadow steppes of the Altai-Sayan mountain region
- All. *Aconito barbati-Poion transbaicalicae* Korolyuk & Makunina 2001c – Meadow steppes and steppe meadows of the Altai-Sayan mountain region
- All. *Veronico incanae-Helictotrichion desertorum* Korolyuk 2010a – Steppes and their petrophytic variants of the Altai-Sayan mountain region
- All. *Rosion pimpinellifoliae* Korolyuk 1997 – shrub steppes of the foothills of the Western Altai.
- Order *Helictotricho-Stipetalia* Toman 1969a – Continental steppes of Northern Kazakhstan, the Southern Urals and Western Siberia
- All. *Helictotricho desertori-Stipion rubentis* Toman 1969b – Continental steppes of Northern Kazakhstan, the Southern Urals
- All. *Plantagini-Calamagrostion epigei* Royer 1991c – Steppes of forest-steppe zone of Trans-Urals and Western Siberia;
- All. *Stipion korshinskii* Toman 1969c – Continental dry steppe of Northern Kazakhstan and South Urals;
- All. *Agropyron pectinati* Golub & Uzhmetskaya 1991d – Desert steppes on slightly saline soils of the Middle Volga

- Class *Helianthemo-Thymetea* Romashchenko, Didukh & Solomakha 1996a – Xero- and mesoxerothermic evergreen shrub communities are usually dominated by *Lamiaceae* species on dry, stony, non-saline and nitrate-poor calciferous soils in the southwestern part of the Central Russian Upland
- Order *Thymo cretacei-Hyssopetalia cretacei* Didukh 1989b – Xerothermic shrub communities on chalk outcrops in the southwestern part of the Central Russian Upland
- All. *Artemisio hololeuca-Hyssopion cretacei* Romashchenko et al. 1996b – Communities on chalk outcrops in the southwestern part of the Central Russian Upland
- All. *Centaureo carbonatae-Koelerion talievii* Romashchenko et al. 1996c – Grasslands of the Central Russian Upland
- All. *Euphorbio cretophilae-Thymion cretacei* Didukh 1989c – Cretaceous outcrop communities in the lower part of the Seversky Donets river basin
- Class *Festucetea vaginatae* Soo ex Vicherek 1972a – Continental psammophytic steppes and dry meadows
- Order *Festucetalia vaginatae* Soo 1957 – Continental psammophytic steppes and dry meadows of Europe
- All. *Festucion beckeri* Vicherek 1972b – Grass communities on sandy and sandy loam soils of the steppe zone of southeast Europe
- Class *Koelerio-Coryneporetea* Klika in Klika & Novak 1941 – Pioneer vegetation on dry poorly developed sandy soils and outcrops of acidic habitats.
- Order *Coryneporetalia canescentis* Klika 1934 – Pioneer psammophytic communities on poorly developed sandy soils
- All. *Corynephorion canescentis* Klika 1931b – the same characteristic as for the order
- Order *Trifolio arvensis-Festucetalia ovinae* Moravec 1967 – Subcontinental and continental psammophytic steppes of Europe and Western Siberia:
- All. *Koelerion glaucae* Volk 1931c – Xerophytic communities on neutral, stabilized sands
- All. *Armerion elongatae* Pötsch 1962a – Dry psammophytic meadows on sandy soils
- Class *Sedo-Scleranthetea* Br.-Bl. 1955 – Succulent communities on unformed soils underlain by weathered rocks
- Order *Sedetalia hybridi* Ermakov prov. – Succulent communities in Altai-Sayan mountain region
- All. *Sedion hybridi* Ermakov, Chytrý & Valachovic 2006a – Communities of succulents of forest-steppe and steppe belts
- Class *Calluno-Ulicetea* Br.-Bl. & Tx. ex Klika & Hadač 1944b – Heathlands on poor acidic soils of plains and low mountains of Europe.
- Order *Nardetalia strictae* Preising 1950 – the same characteristic as for the class
- All. *Violion caninae* Schwickera 1944c – Acidic pastures in the plains and low mountains
- All. *Deschampsio-Anthoxanthion* (Du Rietz 1942) Dahl 1957 – Chionophytic meadows and shrub-grass communities of places with late melting snow in the mountain and zonal tundra of Fennoscandia
- All. *Nardo-Caricion rigidae* Nordhagen (1936) 1943 – Chionophytic meadows of the timberline of the mountain and zonal tundra of Fennoscandia
- Class *Trifolio-Geranietea sanguinei* T. Müller 1962b – Meadow communities of forest edges and woodlands
- Order *Origanetalia vulgaris* T. Müller 1962c – Mesophilic meadow communities of forest edges and woodlands
- All. *Trifolion medii* T. Müller 1962d – Mesophytic forest edge communities
- All. *Geranion sanguinei* Tx. in T. Müller 1962e – Xeromesophytic communities of thermophilic herbaceous plants of the forest edges and woodlands open to the sun
- Class *Cleistogenetea squarrosae* Mirkin & al 1992 – Steppes of Eastern Siberia, Central and East Asia.
- Order *Festucetalia lenensis* Mirkin in Gogoleva et al. 1987b – Moderately dry meadow steppes of Southern Siberia and Inner Asia
- All. *Helictotrichion sellelliani* Hilbig 2000a – Typical meadow steppes of Transbaikalia and Eastern Mongolia
- All. *Stellerion chamaejasmeae* Korolyuk 2002a – Petrophytic meadow steppes of Transbaikalia and Eastern Mongolia
- All. *Filifolion sibirici* Akhtyamov ex Korolyuk 2002b – Meadow steppes of Lesser Khingan
- All. *Pulsatillion flavescens* Mirkin in Gogoleva & al 1987c – Meadow steppes of Central Yakutia
- All. *Elytrigio jacutori-Dracocephalion palmati* Sinelnikova 2009c – Extrazonal meadow steppes of the Far North-East of Asia
- All. *Festuco valesiaca-Caricion pediformis* Ermakov, Larionov & Polyakova 2012
- All. *Eritrichio pectinati-Selaginellion sanguinolentae* Ermakov, Chytrý & Valachovic 2006b – Petrophytic meadow steppes of the steppe and forest-steppe zones of the Altai-Sayan mountain region.
- Order *Stipetalia krylovii* Mirkin in Gogoleva et al. 1987d – Floristically extremely poor extrazonal steppes of the middle taiga subzone of Central Yakutia
- All. *Stipion krylovii* Mirkin in Gogoleva et al. 1987e – the same characteristic as for the order
- All. *Psatyrostachion juncea* Mirkin et al. 1987f – Dry steppes on eroded slopes in Central Yakutia
- Order *Cleistogenetalia squarrosae* Mirkin et al. ex Ermakov 2012b – Steppes of Southern Siberia and Central Asia
- All. *Poo attenuatae-Cleistogenion squarrosae* Mirkin et al. ex Ermakov 2012c – Daurian and Eastern Mongolian moderately dry steppes;
- All. *Thymion gobici* Mirkin in Kashapov et al. ex Hilbig 2000b – Petrophytic steppes of Transbaikalia and Eastern Mongolia.
- Order *Kochio prostratae-Stipetalia krylovii* Ermakov 2012d – Dry and desert steppes of Southern Siberia and Mongolia
- All. *Kochio prostratae-Stipion krylovii* Ermakov 2012e
- All. *Stipion orientalis* Korolyuk & Makunina 2009d – Petrophytic dry and desert steppes of the Altai-Sayan mountain region
- All. *Convolvulo ammannii-Stipion krylovii* Mirkin et al. ex Ermakov 2012f – Dry steppes of Southern and Eastern Mongolia

- Class *Stipetea glareosae-gobicae* Hilbig 2000c – Desert steppes of Central Asia
 Order *Allietalia polyrrhizi* Hilbig 2000d – the same characteristic as for the class
 All. *Allion polyrrhizi* Hilbig 2000e – the same characteristic as for the order
- Class *Artemisio santolinifoliae-Berberidetea sibiricae* Ermakov, Chytrý & Valachovic 2006c – Mountain communities of rocky screes of the steppe and forest-steppe zones of Central and North Asia
 Order *Artemisio santolinifoliae-Berberidetalia sibiricae* Ermakov, Chytrý & Valachovic 2006d – the same characteristic as for the class
 All. *Artemision rutifoliae* Ermakov, Chytrý & Valachovic 2006e – Rocky communities of steppe and desert-steppe zones
 All. *Ulmion pumilae* Mirkin et al. ex Hilbig 2000f – Shrubs on screes in the steppe belt of Southern Transbaikalia and Eastern Mongolia
- Class *Brometea korotkyi* Hilbig & Korolyuk 2000g – Xerophytic sand steppes of the Ulsu-Nur Basin
 Order *Brometalia korotkyi* Hilbig & Korolyuk 2000h – the same characteristic as for the class
 All. *Bromion korotkyi* Hilbig & Korolyuk 2000i – the same characteristic as for the order
 All. *Oxytropidion lanatae* Chytrý, Pesout & Anenkhonov 1993b – Sand steppes of the Baikal region
- Class *Festuco-Puccinellietea* Soo ex Vicherek 1973a – Halophytic communities
 Order *Festuco valesiacae-Limonietalia gmelinii* Mirkin in Golub & V. Solomakha 1988c – Halophytic steppes of Northern Eurasia
 All. *Festuco valesiacae-Limonion gmelinii* Mirkin ex Golub & V. Solomakha 1988d – Halophytic steppes of Southern Ural and Northern Kazakhstan
 All. *Artemision nitrosae* Korolyuk in Korolvuk & Kipriyanova 1998 – Halophytic steppes of south of the West Siberian Plain
 All. *Limonion tomentelli* Agafonov & Golub in Golub 1994a – Halophytic steppes of chernozem regions of the European part of Russia

Abstract

Kazakhstan and Middle Asia comprise 4 million km² of plains, uplands and tall mountain ranges in the core of the Eurasian continent. The region's semi-arid climate, grazing pressure by wild and domestic ungulates, and long pastoral tradition, have given rise to a variety of open habitat types and a distinct flora and fauna. Grasslands and shrublands are a natural and dominant vegetation type in the forest-steppe and steppe zone of northern and central Kazakhstan, as part of the Eurasian grassland biome. In Middle Asia, grasslands and shrublands are widespread habitat types in the Tian Shan, Pamir-Alai and Pamir—mountain systems that have been recently acknowledged as a global biodiversity hotspot. Here, grasslands and shrublands are often semi-natural, formed by a long practice of logging, burning and domestic livestock grazing, and comprise a variety of vegetation types, including Eurosiberian meadows and steppe, Irano-Turanian semi-savanna and thermophilous shrublands. The most serious threats to grassland biodiversity and ecosystem functioning are habitat degradation, including conversion to cropland, pollution, urban development, under- and overgrazing, and illegal hunting. Notwithstanding these threats, Kazakhstan and Middle Asia still harbor vast areas of public, unfenced grasslands and shrublands that are traditionally managed and often embedded in regions with low human density. This makes the region a globally important area for biodiversity conservation.

Delimitation and Physiogeography of the Region

Kazakhstan and Middle Asia form a continental area of 4 million km² (1.5 million square miles), with 97% of the territory belonging to the Asian and 3% to the European continent. The region borders on Russia in the north, China in the east, the Caspian Sea in the west, and Pakistan and Afghanistan in the south, and spans approximately 2000 km of latitude and 2900 km of longitude. In political terms, the region is divided among the countries of Kazakhstan, Kyrgyzstan, Tajikistan, Turkmenistan, and Uzbekistan. Middle Asia has been defined by Soviet geographers as a region comprising the four latter countries and southern Kazakhstan (approximately south of the 48° latitude, stretching from the Caspian Sea to the border of China; [Rachkovskaya et al., 2003](#)). In the last three decades, the term Central Asia has been increasingly used to describe the region covered here and neighboring western China and Mongolia. However, we restrict the term Central Asia more narrowly to the latter region (in line with [Rachkovskaya et al., 2003](#)), which is not treated in this article and separated from Middle Asia by the Dzhungar Alatau and Tian Shan mountains.

The northern plains and gentle uplands of Kazakhstan are dominated by forest-steppe and steppe (dry grasslands), while Middle Asia encompasses lowland deserts and tall mountains, such as the Altai, Tarbagatai, and Dzhungarian Alatau in the east, and the Tian Shan, Pamir-Alai, and Pamir in the south. The mountains of Middle Asia are among the tallest worldwide, with some peaks exceeding 7000 m.

The runoff from the region's uplands and mountain systems drains into rivers that discharge into the Arctic Sea or the endorheic basins of the Aral and Balkhash Seas. The Zhetisu region north of the Tian Shan, and the Amu Darya and Syr Darya rivers west of the Tian Shan form large floodplains. However, the two latter have been strongly reduced in size due to intensive crop-irrigation further upstream ([Peterson, 1993](#)). The plains and uplands of Kazakhstan are rich in freshwater and saline wetlands.

The region's climate is strongly continental and shaped by its landlocked position in the heart of the Asian continent. In general, it is characterized by high solar insolation, relatively low precipitation and a strong amplitude of daily and seasonal temperatures. According to the recent Köppen global climate classification (Beck et al., 2018), the plains and uplands of Kazakhstan, and central mountains of Middle Asia, have cold semi-arid (climate zone code: Bsk) and desert (Bwk) climates. The outer northern and western mountain ranges of the Altai, Tian Shan, Pamir-Alai, and Pamir intercept precipitation carried by Westerlies and show a humid continental climate (Dsa, Dsb, Df). The foothills of the western Tian Shan and south-western Pamir-Alai are the only areas in the region with a Mediterranean climate (Csa). By comparison, the innermost and tall mountain ranges that stretch from the Altai in the north-east to the Pamir in the south display tundra (ET) climate with low temperatures year-round.

Biogeography, Flora and Fauna

Forest-Steppe and Steppe Zones

The grasslands of northern and central Kazakhstan are part of the Eurasian steppe biome and the Black Sea-Kazakhstan steppe sub-region (Lavrenko et al., 1991; Bragina et al., 2018). They span two biogeographic zones that are aligned as latitudinal belts (Rachkovskaya et al., 2003). The forest-steppe zone comprises the northern tip of Kazakhstan. As part of the West Siberian Lowlands, it is made up of gentle topography covered by a mosaic of steppe grasslands, shrublands, meadows, and woodlands. In a recent overview of forest-steppe zones, Erdős et al. (2018) assigned northern Kazakhstan to the West Siberia and North Kazakhstan forest-steppe region. A total of 48 species of mammals occur here (Rodentia: 21, Carnivora: 10, Insectivora: 7, Chiroptera: 5, Artiodactyla: 3, Lagomorpha: 2), including Siberian roe deer (*Capreolus pygargus*), moose (*Alces alces*), northern white-breasted hedgehog (*Erinaceus roumanicus*), northern birch mouse (*Sicista betulina*), and bank vole (*Myodes glareolus*). A total of 167 nesting bird species (most of which are bound to woodlands, shrublands, and lakes) and seven reptile species (mostly snakes) inhabit this region. Common amphibians are European green toad (*Bufo viridis* complex), moor frog (*Rana arvalis*), common frog (*Rana temporaria*), and Siberian newt (*Salamandrella keyserlingii*). Due to the region's fertile chernozem soils and moderate climate, approximately 60–90% of grasslands have been plowed (Semenov, 2012; Kraemer et al., 2015).

The adjacent and more arid steppe zone is found further south, approximately at latitudes 48°–52°. Its vegetation is dominated by drought-tolerant steppe and—more rarely—shrublands on chernozem and kastanozem (chestnut) soils. This zone is home to 73 species of mammals (Rodentia: 35, Carnivora: 13, bats: 9, Insectivora: 7, Artiodactyla: 5, Lagomorpha: 4 species). Characteristic species of mammals are saiga antelope (*Saiga tatarica*), marmots (*Marmota bobak*, *M. baibacina*), sousliks (*Spermophilus pygmaeus*, *S. major*, *S. erythrogenys*), mole vole (*Ellobius talpinus*), steppe lemming (*Lagurus lagurus*), steppe fox (*Vulpes corsac*), steppe polecat (*Mustela eversmanii*), and steppe and kazakh pikas (*Ochotona pusilla*, *O. opaca*). Characteristic birds are little bustard (*Tetrax tetrax*), demoiselle crane (*Anthropoides virgo*), steppe eagle (*Aquila nipalensis*), long-legged buzzard (*Buteo rufinus*), several species of *Calandrella* and *Melanocorypha* larks (including sub-endemic black lark *Melanocorypha yeltoniensis* and white-winged lark *Melanocorypha leucoptera*; the latter considered as *Alauda leucoptera*—Alström et al., 2013), wheatear species (specifically isabelline wheatear, *Oenanthe isabellina*, pied wheatear, *O. pleschanka*), and red-headed bunting (*Emberiza bruniceps*). The Naurzum Nature Reserve, a protected area in the steppe zone of northern Kazakhstan, provides habitat for 316 bird species, of which 168 are nesting (Bragin and Bragina, 2014, 2017). Six species of amphibians and 14 species of reptiles are found in the steppe zone of Kazakhstan. Rain-fed crop agriculture and animal husbandry dominate the regional land-use.

In the past, the forest-steppe and steppe of Kazakhstan have been grazed by many wild ungulates, rodents, and lagomorphs, which have likely been keystone mutualists and ecological engineers in steppe ecosystems (Murdoch et al., 2009; Abaturov and Kulakova, 2010). Common ungulates included wild horse (now extinct), kulan (extinct), saiga antelope (critically endangered), and the argali wild sheep (near threatened). Populations of ungulate grazers have strongly decreased in the last three centuries due to hunting, grassland conversion into crop land, and competition with livestock for pastures. While the populations of wild ungulates have decreased, those of many rodents and lagomorphs have stayed viable (Kamp et al., 2016).

About 2000 vascular plants are known to grow in the forest-steppe and steppe zones of Kazakhstan, with about 1.5% of the total flora endemic to the region (Rachkovskaya and Bragina, 2012; see below for a more detailed outline of prevalent species). The steppe zone borders on the desert zone further south (not covered in this article).

Middle Asia

The biogeographic make up of Middle Asia is shaped by strong differences in topography and macroclimate. The plains are dominated by South Turanian deserts (not covered here), which border on an extensive mountain region with a wide range of different habitat types, including grasslands, meadows, semi-savanna, and shrublands. Based on the prevalent flora, the mountain region of Middle Asia can be divided into four provinces (Rachkovskaya et al., 2003; the Kopet Dag is not covered here).

- (1) The Dzhungar-North Tian Shan province includes the northern ranges of the Tian Shan and parts of the Dzhungar Alatau and central Tian Shan. These ranges intercept moist air from the Westerlies and are characterized by *Picea schrenkiana* forests (sometimes only as fragments), Eurosiberian meadows on northern slopes and gentle shoulders in the mid-altitudinal belts, and steppe grasslands with Eurasian bunchgrasses in the foothills and on southern exposed slopes (Rachkovskaya et al., 2003).

- (2) The Middle Asian mountain province encompasses the western Tian Shan, the Karatau mountains, the western central Tian Shan, and the mountains of western Tajikistan. Being mostly oriented to the west, they similarly intercept precipitation from the Westerlies. Bedrock is dominated by limestone. The montane belt is commonly formed by open juniper forests while spruce is rare. The mountains of the Fergana valley (Chatkal and Fergana ranges), and the Gissar and Darvaz ranges, are covered by wild fruit forests with walnut (*Juglans regia*), Turkestan maple (*Acer turkestanicum*), and wild apple (*Malus sieversii*). The low mountains and foothills are dominated by semi-desert that encompasses many annuals and geophytes with a peak growing and flowering season in late winter and spring. Steppe vegetation is rare (Rachkovskaya et al., 2003).
- (3) The Central Asian mountain province is found at the south-eastern edge of the region covered in this article and includes the high mountains and plateaus of the eastern central Tian Shan and eastern Pamir. This region is characterized by strong aridity since precipitation carrying winds are blocked from this region by mountain chains further north, west and south. Forest vegetation is almost absent. Instead, mountain deserts play an important role at the lowest and middle altitudinal belts. Cryophytic cushion communities are found at the highest elevations (Rachkovskaya et al., 2003).
- (4) The North Hindukush Province comprises the south-western Gorno-Badakhshan region in southern Tajikistan and some neighbouring territories outside of the chapter's focus. Lower altitudes are covered by semi-desert and xerophytic shrublands, in which sagebrush species play an important role. They are replaced by cryophytic cushion communities at higher elevations (Rachkovskaya et al., 2003).

The mountains of Middle Asia and southern Kazakhstan are a global biodiversity hotspot ("Critical Ecosystem Partnership Fund," www.cepf.net/our-work/biodiversity-hotspots). Approximately 10,000 vascular plant species can be found here (Kamelin, 2017). Although detailed data on species numbers across habitats are missing, we assume that a large portion of taxa grows in open habitat types because they are widespread in this region and occur over a wide variety of bedrock and soil types. Regional plant endemism is high: approximately half of the species pool and approximately 100 genera of flowering plants are endemic (Kamelin, 2017). Regional studies report endemism rates of 14% (Aksu-Jabagly Nature reserve, calculated from Karmysheva, 1973), 10% (Uzbekistan, Tojibaev, et al. *in prep*, cited in Sennikov et al., 2016) and approx. 30% (Nowak et al., 2011). Some plant genera are particularly rich in endemics, such as *Allium*, *Astragalus*, *Cousinia*, and *Oxytropis*. The high rate of endemism in the mountain regions of Middle Asia is probably due to niche diversification in the Pleistocene when environmental conditions repeatedly shifted between dry and humid (Bagheri et al., 2017).

Vascular plants with an Irano-Turanian distribution make up a large percentage of the regional flora (c. 60% of the total regional species pool, e.g. *Acantholimon diapsenioides*, *Carex pamirensis*, *Ranunculus badachschanicus*). Mediterranean species (10%) grow mainly in lowlands and montane belts of the western and south-western ranges, and include species like *Avena meridionalis*, *Cressa cretica*, and *Parietaria serbica*. Euro-Siberian species are particularly common in the northern ranges of the Tian Shan and Dzhungar Alatau (e.g. *Dactylis glomerata*, *Fragaria viridis*, *Stipa capillata*). The remaining part of the species pool is made up of circumpolar (e.g. *Parnassia palustris*), East Asian (Oriental) (e.g. *Eucommia ulmoides*), Indo-Chinese (e.g. *Sphenoclea zeylanica*), tropical and subtropical (e.g. *Ludwigia perennis*), Saharo-Sindian (e.g. *Nanorrhinum ramosissimum*), arctic-alpine (e.g. *Carex microglochin*, *Lloydia serotina*) and Himalayan plants (e.g. *Aconitum rotundifolium*, *Alopecurus himalaicus*).

Middle Asia has a rich fauna. A total of 543 migratory and non-migratory bird species are known from the area, including the rare white pelican (*Pelecanus onocrotalus*), Egyptian vulture (*Neophron percnopterus*), and Asian paradise flycatcher (*Terpsiphone paradisi*; Ryabitshev, 2019). The Aksu-Jabagly Nature Reserve, Middle Asia's oldest protected area, lists 44 mammal species, including the Indian crested porcupine (*Hystrix indica*), argali (Marco-Polo sheep, *Ovis ammon polii*), Himalayan brown bear (*Ursus arctos isabellinus*), and the critically endangered snow leopard (*Uncia uncia*) (Beg, 2009). A mixture of crop agriculture and pastoralism has been practiced for millennia in the fertile foothills and lowlands (Spengler et al., 2014) and the region has been traversed by the Silk Road network in the past (Spengler, 2019). Today, the western and northern Tian Shan has a disproportionately high human density and includes large metropolitan areas, like Almaty, Bishkek, and Tashkent. Despite the recent growth in urban areas, pastoralism still plays an important role in mountainous Middle Asia.

Grassland Origin

The Kazakh forest-steppe and steppe are considered to be of natural origin, attributed to the region's semi-arid climate that established since the Indian and Eurasian tectonic plates collided in the Cenozoic. The relatively young mountains of the Tian Shan, Pamir-Alai, and Pamir cut the region off from the moist southern monsoon (Kamelin, 2017). Wild ungulates have likely also played an important role in reducing shrub and tree encroachment. After the emergence of mobile pastoralism approximately 5000 years before present (BP), the roaming herds of wild ungulates were replaced by domestic ungulates (Frachetti, 2012). Today, the vegetation of forest-steppe and steppe is still affected to a large degree by livestock grazing and wildfires.

The origin of grasslands in the mountain regions of eastern and southern Kazakhstan and Middle Asia is more complex and likely of both anthropogenic and natural origin. Here, open coniferous and deciduous forests prevail in the montane belt, especially in the outer mountain ranges that receive the highest amounts of precipitation in the region. Local nomads burned and logged forests and shrublands in mountains to expand grasslands (Elenevskiy, 1940; Dakhsleyger, 1980). Although exact data are missing, we can assume that a high percentage of hay meadows and pastures in the foothills and the mid-elevational zone are of

anthropogenic origin. However, the steppe communities on southern-exposed slopes and alpine grasslands are likely of natural origin, favored by a microclimate that limits tree growth.

Typology of Communities

Forest-Steppe and Steppe Zones

Grasslands are a dominant vegetation type in the forest-steppe and steppe zones of northern Kazakhstan (Fig. 1). The forest-steppe zone is a transitional region between the Siberian taiga in the north and steppe in the south and is comprised of a mixture of grasslands, meadows and woodland groves. As precipitation decreases further south in the steppe zone, tree growth becomes limited and open habitats—most importantly dry grasslands—dominate the landscape.

Temperate-dry rich forb—feathergrass meadow steppes on haplic chernozem are located along the southern periphery of the West Siberian Lowland. These communities are rich in forbs (e.g. *Filipendula vulgaris*, *Iris ruthenica*, *Lathyrus pratensis*, *Peucedanum*

Fig. 1 Grasslands and shrublands of the plains and uplands of Kazakhstan. (A)—Steppe with *Stipa capillata* on sandy soils (B)—Shrubland with prostrate *Juniperus sabina* in the steppe zone (both in the Naurzum Nature Reserve) (C)—Desert steppe with *Stipa lessingiana* and *S. sareptana* (Mugodzhary Hills, western Kazakhstan) (D)—Dry steppe with *Spiraea hypericifolia* (Central Kazakhstan Upland, Karaganda region) (E)—Desert steppe with *Stipa sareptana* and *Agropyron desertorum* (Sub-Urals Plateau, western Kazakhstan) (F)—Dry xeric forb—bunchgrass steppe with *Caragana pumila* shrubs (Dogalan Hills, east Kazakhstan Uplands). Photos by V. Wagner (A), T. Bragina (B), and I. Smelansky (C–F).

morisonii, *Phlomis tuberosa*, *Veronica spuria*) and feathergrasses (e.g. *Stipa pennata*, *S. zaleskii*). Further south, in the plains of the West Siberian Lowland, the Trans-Ural Plateau and the northeast Kokshetau uplands, steppe is dominated by dry forb—feather grass communities with *Stipa zaleskii* and *Festuca valesiaca* as dominant plants, and *Koeleria cristata* as a co-dominant. On calcareous soils, *Stipa korshinskiyi* is a characteristic dominant plant and *Stipa lessingiana* a co-dominant. Temperate dry-bunchgrass steppes on dark chestnut soils are common on the plains of the Sub-Ural and Turgay Plateau, in the eastern periphery of the West Siberian Lowland, and the plains among the hills of the Central Kazakhstan. Here, *Stipa lessingiana* prevails with an admixture of small forbs. Dry xerophytic forb—bunch grass steppes on chestnut soils are widespread in the Sub-Ural and Turgay Plateau (with *Festuca valesiaca*, *Galatella divaricata*, *G. tatarica*, *Phlomis agraria*, *Stipa lessingiana*, *Tanacetum achilleifolium*). Steppe on sandy soils are characterized by *Stipa capillata*, *S. borysthenica*, and *Helichrysum arenarium*.

The most southern zonal steppe grasslands are made up of desert sagebrush—bunch grass steppes on light chestnut soils. They are dominated by the drought resistant *Stipa sareptana* and are found in the Caspian Lowlands, the Sub-Ural and Turgay Plateaus, the Mugodzhary Hills, the Central Kazakhstan Uplands, and the Kulunda Plain. Desert steppe is the most xeric among zonal steppe grasslands. It is found between latitudes N48–49° to N46–47° and is associated with light kastanozem soils. Its communities are dominated by *Stipa sareptana* and *S. kirghisorum* on sandy and clay-rich soils and *Stipa caucasica* and *S. orientalis* on rocky soils and bedrock outcrops. These grasslands can occur interspersed with dwarf shrub deserts (dominated by *Artemisia* and *Chenopodiaceae* species). They are distributed as a solid belt on plains and uplands from the Caspian Lowland in the west to the Zaisan Depression in the east. Dry saline habitats with deep water horizons on river and lake terraces are occupied with specific *saz* steppe communities commonly dominated by giant bunchgrass *Neotrinia* (= *Achnatherum*) *splendens*, *Leymus* spp. (on sandy soils: *Leymus racemosus*, giant grass), and *Iris halophila*.

Depressions and riparian corridors are covered by reed beds with rhizomatous grasses, sedges, rushes and mesic to wet meadows with e.g. *Filipendula ulmaria* and *Sanguisorba officinalis*. As salinity increases, meadows become dominated by more salt-tolerant species such as *Glycyrrhiza uralensis*, *Hordeum brevisubulatum*, *Limonium gmelinii*, and *Puccinellia distans* (Kalinina, 1961). Compared to steppe grasslands, reed bed and meadow vegetation in the forest-steppe and steppe zones of Kazakhstan has not been well studied.

Shrubs can occur interspersed as single individuals in grasslands or can form communities corresponding to the grassland types outlined above. For instance, thickets with *Rosa* spp., *Cytisus* spp., *Lonicera tatarica*, *Spiraea crenata*, and *Padus racemosa* are characteristic for meadow steppe. *Spiraea hypericifolia* and *Caragana frutex* form extensive shrublands in dry steppe. Several species of *Atraphaxis* (*A. decipiens*, *A. spinosa*, *A. laetevirens*) and *Caragana* (e.g. *C. balchaschensis*, *C. bongardiana*, *C. leucophloea*, *C. pumila*) are characteristic for desert steppe shrublands. Steppes with the sub-endemic *Calophaca soongorica* shrub are typical for the Tarbagatai foothills in eastern Kazakhstan. Rocky habitats in uplands and foothills can have a high cover of steppe shrublands, including communities with *Cotoneaster melanocarpa*, *Lonicera microphylla*, *Juniperus sabina*, or *Ephedra* species (e.g. *E. equisetina*). Saline depressions and river and lake terraces of the southern half of the steppe zone are often dominated by *Halimodendron halodendron* and *Tamarix* spp. shrublands.

Middle Asia

The grasslands and shrublands of Middle Asia display a rich array of different habitat types due to the region's pronounced differences in climate and topography (Fig. 2). The foothills of the western Tian Shan and Pamir-Alai are covered by ephemeral semi-desert on thick loam deposits, dominated by annual grasses (e.g. *Bromus danthoniae*, *B. tectorum*, *Poa bulbosa*) and sedges (e.g. *Carex pachystylis*) (Korovin, 1961). With increasing elevation, it transitions into a taller drought tolerant vegetation type dominated by grasses (*Agropyron trichophorum*, *Bothriochloa ischaemum*, *Hordeum bulbosum*, *Lolium persicum* and *Trachymia distachya*) or Apiaceae species (*Ferula tenuisecta*, *Prangos pabularia*), often interspersed with shrubs (e.g. *Rosa kokanica*) or small trees (e.g. *Celtis caucasica*). This vegetation comprises various open and thermophilous plant community types on xeric sites, such as on rocky soils and southern or western slopes. This habitat type is not related to the Eurasian dry grasslands and meadows but is rather Irano-Turanian vegetation, being found only in the western mountain ranges of Middle Asia, Afghanistan, Iran and Turkey. The high cover of tall and drought tolerant Apiaceae species and grasses, combined with interspersed shrubs or trees, has puzzled Soviet botanists as it did not match their concept of a typical grassland, as exemplified by the Eurosiberian steppe or meadow. Hence, they used different names for this vegetation type, e.g. "savannoides," "semi-savanna," or "turanian steppe" (Korovin, 1962; Karmysheva, 1973; Pavlov, 1980).

Wind-exposed slopes in the northern and western mountain ranges are often covered by steppe with tussock grasses (e.g. *Festuca valesiaca*, *Helictotrichon hookeri*, *Koeleria cristata*, *Stipa krylovii*). This vegetation type closely resembles the steppes of the northern plains of Kazakhstan and is used foremost for livestock grazing (Korovin, 1962).

The precipitation-rich northern and western ranges of the Tian Shan are also home to meadow-steppe and meadows on deep brown soils in the montane and subalpine belts, dominated by Eurosiberian species, like *Bromus inermis*, *Dactylis glomerata*, *Galium verum*, and *Poa angustifolia* (Karmysheva, 1961; Wagner, 2009). Given their productivity and prevalence of palatable species, these mesic grasslands are often used for traditional hay making.

Shrublands are widespread in the mountains of Middle Asia. They encompass thermophilous communities (referred to as "shiblyak" in Slavic languages), low-growing juniper shrublands, and dwarf shrub communities (Korovin, 1962). Shiblyak vegetation occurs primarily in the western Tian Shan and Pamir-Alai, on rocky soils from lower elevations to the lower montane belt. Common shrubs include wild pistachio (*Pistacia vera*), elm-leaved sumach (*Rhus coriaria*), jujube (*Ziziphus jujuba*), thorny almond (*Amygdalus*

Fig. 2 Grasslands and shrublands of Middle Asia. (A)—Mesic meadows and *Picea schrenkiana* forests (Trans-Ili Alatau, northern Tian Shan, Kazakhstan) (B)—Semi-savanna with *Ferula tenuisecta* (western Pamir-Alai, Tajikistan) (C)—Mountain steppe interspersed with *Picea schrenkiana* fragments (eastern Kyrgyzstan) (D)—Mountain steppe with *Stipa drobovii* (Fon Mountains, western Pamir-Alai) (E)—Shiblyak vegetation with *Rhus coriaria* (Hissar mountains, western Pamir-Alai) (F)—Haymaking in the southern Naryn region (Kyrgyzstan). Photos by V. Wagner (A), A. Nowak (B, D, E), and K. Vanselow (C, F).

spinosissima), wild pomegranate (*Punica granatum*), and Jerusalem thorn (*Paliurus spina-christi*). Shiblyak is rich in annuals and geophytes and occurs interspersed with semi-deserts and semi-savanna (see above). It has been suggested that these shrublands, together with open deciduous woodlands, are the potential natural vegetation of the lower montane and colline belt in the western Tian Shan and Pamir-Alai, and that their spatial extent has been much reduced due to wood removal (Karmysheva, 1982).

Shrublands at higher elevations comprise thickets of procumbent *Juniperus pseudosabina*, especially in the northern and western Tian Shan. Rose thickets are common in the Tian Shan, Pamir-Alai and western Pamir (e.g. with *Rosa begeriana*, *R. divina*, *R. ecae*, *R. fedtschenkoana*, or *R. maracandica*). The western Pamir is also home to shrub communities with *Amygdalus bucharica* associated with tall herbs (e.g. *Eremurus stenophyllus*) and other shrubs (e.g. *Lonicera persica*), rose communities (e.g. *Rosa kokanica*, *R. webbiana*), associated with *Exochorda alberti*, *Lonicera korolkowii* and tall herbs (e.g. *Aconogonon coriarium*), and *Cotoneaster* communities dominated by *Cotoneaster uniflorus* and *C. multiflorus* associated with *Lonicera microphylla*. Thickets with *Ephedra* spp. can be dominant in more arid mountain ranges (e.g. with *Ephedra intermedia*, *E. glauca* or *E. equisetina* accompanied by shrubs of *Atraphaxis pyrifolia*, *A. seravschanica* and *Sageretia laetevirens*). Dwarf shrub communities are found at high elevations throughout the region's arid mountains (not covered here).

Moist meadows are limited to riparian sites with a high ground water table or accumulations of melting snow. These meadows are dominated by species of sedges (*Carex* spp.) and bog sedges (*Kobresia* spp.) and often degraded due to grazing.

Threats

Habitat degradation and loss is the most serious threat to grasslands and shrublands in the region. This is particularly true for the forest-steppe and steppe zones of Kazakhstan. This area has been traditionally inhabited by mobile pastoralists. When the country became part of the Soviet Union in the first half of the 20th century, the government enforced sedentarization of its nomads. About 254,000 km² of steppe was converted to crop land (foremost for wheat farming) under the Virgin Land Campaign (Peterson, 1993; Semenov, 2012; Kraemer et al., 2015). This land-use transformation resulted in large-scale loss of two zonal types of steppe ecosystems, rich forbs—grass steppe and dry steppe (meadow steppe had been destroyed even earlier, in the start of 20th century). It has contributed to the decline of many steppe species, including the saiga antelope (*Saiga tatarica*, critically endangered), marmots (*Marmota bobac*, *M. baibacina*), many steppe raptors, and great bustard (*Otis tarda*, vulnerable). After the cessation of the Soviet Union, the region experienced a strong economic depression and rural exodus. It is assumed that this trend has fostered undergrazing of steppe grasslands as many wild ungulates are extinct and cannot fill the niche (Kamp et al., 2016). Undergrazing in turn has led to extensive wildfires that became a significant factor in steppe grasslands and shrublands after the year 2000 (Smelansky et al., 2015; Kamp et al., 2016). Many steppe species, including feathergrass (*Stipa* spp.), demoiselle crane (*Grus virgo*), and different larks (Alaudidae), benefited from this land-use change. Some others, meanwhile, faced new threats. Populations of red-cheeked sousek (*Spermophilus erythrogenys*) and sociable lapwing (*Vanellus gregarius*, critically endangered since 2004) have almost collapsed in 1990–2000s, and the steppe eagle (*Aquila nipalensis*, recognized as endangered in 2015) has declined significantly (Kamp et al., 2011, 2016; Sheldon et al., 2013; Karyakin, 2013, 2018).

The official lists of rare and endangered species of Kazakhstan include 370 species of vascular plants, three bryophyte species, one lichen species, 13 fungus species, and 224 taxa of animals, including 18 fish, three amphibian, 10 reptile, 57 bird, and 40 mammal species (128 vertebrate species in total), and 96 invertebrate species (2 annelid, 6 mollusc, 1 crustacean, 2 arachnid, and 85 insect species) (Annexes No. 5 and 6 to 2012 Government Resolution No. 1413).

In Middle Asia, grasslands and shrublands face a multitude of threats and pressures. The rise in human population and associated urban development, coupled with land conversion and organized hunting programs, lead to the extinction of keystone species, like the Caspian tiger (*Panthera tigris virgata*) and Asiatic cheetah (*Acinonyx jubatus venaticus*) in the desert lowlands. Land conversion also resulted in soil erosion and salinization, a decline of groundwater levels, and the disappearance of the Aral Sea. Rural population numbers are still high. For instance, 73.6% of the population in Tajikistan lives outside of cities (Kamoliddinov et al., 2012). Here, direct human impacts, such as overgrazing, soil erosion or failures in irrigation are major environmental threats, with 30–35% of land being extremely degraded (Safarov et al., 2014). Pressure on natural resources and human induced land cover change strongly increased in the recent past, especially after the collapse of the Soviet Union and the associated demand for fuel and agricultural products (Vanselow et al., 2012; Mislimshoeva et al., 2013; Kraudzun et al., 2014; Yu et al., 2019). In the West Pamir, for example, the number of cattle increased since 1990 (Qonunov, 2010), which resulted in overstocking and an expansion of unpalatable and harmful plants (Akhmadov et al., 2006). For the same region, Breckle and Wucherer (2006) report a human-induced decline of juniper woodland and steppes during the last decades. This trend will be intensified by climate change. For example, Seim et al. (2016) disclose that in the northern Pamir-Alai and Tian Shan mountains in Kyrgyzstan and eastern Uzbekistan increasing temperatures and changing precipitation patterns during the past eight decades led to increased drought stress in juniper trees. Several other studies discuss increased severity of weather conditions, such as erratic rainfall, or changes in the hydrology due to increased snowmelt with torrential runoff as an impact, in particular for riparian ecosystems and adjacent settlements (Narama, 2001; Breu et al., 2005; Khromova et al., 2006; Kassam, 2009; Kayumov and Rajabov, 2010). Recent persistent threats in some regions of Kazakhstan and Middle Asia encompass uncontrolled pollution by toxic waste released by industry and mining (Peterson, 1993).

Conservation, Restoration and Sustainable Management

Long before the onset of modern conservation, locals had practiced a traditional form of nature conservation in the region through assigned “kuruk” (pronounced “koorook”) areas. Until the 19th century, kuruks were public land where ordinary land use was prohibited, and grasslands reserved for occasional future needs like grazing of cavalry horses for a war campaign or mass hunting (Drobyshev, 2014; Pochekaev, 2016). Modern and science-based conservation was established in the region in the 1920s by the Soviet government (Ziegler, 1990). After their proclamation of independence at the beginning of the 1990s, all countries have maintained a system of protected areas that differ in the degree of protection, with Zapovedniks as the most strictly protected areas (IUCN category I). However, protected areas are not evenly distributed across the region, with major gaps in the western part (Bragina et al., 2018). In the steppe and forest-steppe zones of Kazakhstan the protected area network currently includes five national parks (480,644 ha in total), two strict nature reserves (Zapovedniks, 734,552 ha in total), three state nature reserves (in total 1,429,894 ha), and several wildlife sanctuaries. Most protected areas were established after the year 2000. However, although many are located in the steppe zone, only a small part of these protected areas is covered by grasslands and shrublands. Instead,

most of their area are covered by azonal forests, wetlands, sand and saline deserts, and other habitat types. In addition, vast areas of montane steppe and desert steppe in East Kazakhstan are protected through the recently established Tarbagatai National Park (143,550 ha) and Arganaty Wildlife Refuge (c. 187,000 ha).

The region comprises three World Natural Heritage Sites: Saryarka—Steppe and Lakes of Northern Kazakhstan (including Naurzum and Korgalzhyn State Nature Reserves, Kazakhstan), Western Tian Shan (a network of protected areas, including 13 in Kazakhstan, Kyrgyzstan, and Uzbekistan), and Tajik National Park (Mountains of the Pamirs) (Tajikistan). The three sites include large areas of mesic, semi-arid, and arid grasslands and shrublands.

The grasslands and shrublands of Kazakhstan and Middle Asia have not been subject to any major restoration efforts because the region still maintains relatively undisturbed ecosystems, thanks to their large area, public ownership and a traditional management regime (Fig. 2F). The collapse of agriculture in the early 1990s in Kazakhstan resulted in abandonment of approximately 12 million hectares of cropland, mainly in the steppe zone, and millions of hectares of rangelands in the both steppe and desert zones (Kamp et al., 2011). Approximately within a decade, the abandoned grasslands spontaneously restored to their optimal conditions and abandoned croplands underwent a succession to secondary steppe-like grasslands. After 2005, a significant part of the spontaneously recovered grasslands was re-plowed or returned into pastoral use. Nevertheless, vast areas of secondary and recovered grasslands and shrublands are still relatively intact.

All countries of Middle Asia have legislations for rangeland use (adopted in 2009 in Kyrgyzstan, and in 2019 in Uzbekistan) based on the principles of sustainable land-use. Although far from being perfectly implemented, this legislation provides an important framework for sustainable rangeland use in the region. Furthermore, wildlife conservation has also received increased attention. The Turkmenian kulan (*Equus hemionus kulan*) has been recently reintroduced and several efforts are being carried out in support of saiga, birds, and snow leopard conservation.

Abstract

Mongolian grasslands and arid rangelands cover 80% of the country's area at an estimated 1.2 million km². They are still relatively intact, with largely natural environmental conditions and natural structure, and the country has declared >17% of its territory as conservation area. The region has an extremely continental climate with absolute temperatures fluctuating between –50 °C and +45 °C, and <350 mm rainfall per year. Botanically, Mongolia is located at the intersection between three different subkingdoms (i.e., the Boreal, Tethyan, and East Asian subkingdoms) of the Holarctic realm. Nomadic herders use these pastures since the Bronze Age and livestock grazing has been the dominant human impact in Mongolian grasslands until now, with the national herd comprising >65 Mio. animals in 2018. Overgrazing has become a major problem in parts of the steppe ecosystem, impacting fauna and flora and leading to a higher vulnerability of herds to mass mortality in harsh winters. Global warming is another major global change impact in Mongolia.

Topography, Climate and Soils

Located between the Russian Federation and the People's Republic of China in the heart of the Asian continent, land-locked Mongolia extends between the latitudes of 41°35'N and 52°09'N (1,259 km) and the longitudes of 87°44'E and 119°56'E (2,392 km). Mongolian steppes span between the Siberian taiga in the north and Gobi Desert in the south, and are part of the largest natural grassland in the world, which Mongolia hosts together with China (Pfeiffer et al., 2018). The Mongolian grasslands and arid rangelands cover 80% of the country's area at an estimated 1.2 million km² (Suttie, 2005). They lie at altitudes between 500 and 2300 m a.s.l. with an average of about 1580 m a.s.l., and comprise several types of grasslands in the main ecoregions: forest steppe, steppe and desert steppe (Table 1). The seemingly "endless" steppes of Mongolia are still relatively intact, with largely natural environmental conditions and natural structure (Batsaikhan et al., 2014). Mongolia's unique location, its pristine ecosystems, and the low population still practicing ancient traditions and the culture of nomadic livestock breeding make it a priority country for the conservation of temperate grasslands, which are at the brink of extinction in many other regions (Henwood, 1998). They are key habitats for threatened animal and plant species and for the sustainable coexistence between humans and nature (Fig. 1).

Three large mountain ranges run through the Mongolian plateau: in the west and in the south the alpine Altai Mountains with their snow-capped peaks reach >4000 m a.s.l. The Khangai Mountains are a broadly arched mountain range stretching 800 km from west to east in central Mongolia. The Khentii Mountains are smaller and lower than the other mountain ranges and extend from northeastern Mongolia to Siberia. The mountains are surrounded by vast steppes that extend into the Gobi Desert in the south, which embraces mosaic patterns of dry vegetation types.

Mongolia has an extremely continental climate with very little rainfall. The temperature fluctuations are enormous, both daily and annually. Seasons change quickly and both spring and autumn are rather short. Winters are long and last from the beginning of November to April, with absolute temperatures between –30° and –40 °C in many regions and as low as –48 °C in the mountains (Dulamsuren and Hauck, 2008). In summer absolute temperatures rise sharply and can reach over +40 °C in the South Gobi. While yearly average temperatures in the whole of Mongolia are around zero degrees, they increase along a north to south gradient e.g., from 1.1 °C in Ulaanbaatar to 4.3 °C in Dalanzadgad (South Gobi) (Pfeiffer et al., 2003).

Table 1 Ecoregions with natural grasslands of Mongolia, and their key environmental, climate and land use characteristics (median and interquartile range based on Hijmans et al. (2005)).

<i>Ecoregion</i>	<i>Forest steppes</i>	<i>Typical steppes</i>	<i>Desert steppes</i>
<i>Estimated grassland extent (Mio. km²)</i>	0.3	0.3	0.4
<i>Elevation (m a.s.l.)</i>			
Median	1850	1100	1400
25–75% quartile	1400–2300	850–1300	1150–1700
<i>Mean annual temperature (°C)</i>			
Median	–2.4	0.4	1.4
25–75% quartile	–5.1 to –0.7	–0.3–1.0	–1.8–3.3
<i>Mean annual precipitation (mm)</i>			
Median	260	220	130
25–75% quartile	200–330	190–250	110–170
<i>Mean precipitation warmest quarter (mm)</i>			
Median	170	150	90
25–75% quartile	120–220	140–180	80–110

Not listed are relatively small areas of alpine steppes in Mongolia (<0.1 Mio. km²). Based on original area estimates for TEOW (Terrestrial Ecosystems of the World Olson et al. (2001)) weighted by an estimated share of grasslands in the TEOW.

**Fig. 1** A Mongolian herder crosses the steppes in winter time. Photo by Nyamsuren Batsaikhan.

The mountain ranges of the Altai, Tien Shan, the Himalayas and the Tibetan Plateau as well as the Great Khingan shield off precipitation from west, south and east. Moisture thus comes in from the northern part of the country, which receives more rainfall (200–350 mm per year) than the central and southern areas at 100–200 and even below 100 mm, respectively. These steep gradients in precipitation and temperature shape a north to south sequence of latitudinal vegetation belts, namely tundra, taiga, forest-steppe, steppe, semi-desert and desert (Lavrenko and Karamysheva, 1993). Tree growth is restricted to the northern borders of Mongolia, and to mountain as well as water surplus areas. In the transition zone of forest steppes trees are only growing on the northern slopes where evaporation is reduced.

More than 50% of the yearly average precipitation falls in summer between early June and late August, resulting in mean monthly precipitation sums of >30 mm, which is enough to sustain grasslands, even in areas with much <150 mm rainfall per year (Pfeiffer et al., 2018). In recent years stratiform rains that provide continuous precipitation that can be absorbed by the ground and become plant available have decreased, while frequency of convective (showery) rains increased; the latter cause intense, short-lasting rainfalls with increased surface runoff and risk of erosion (Vandandorj et al., 2017). High inter-annual variability of the summer rainfall at a local scale limits the continuous use of pasture by herders, who are thus forced to movements and mobile livelihoods. From year to year, annual precipitation totals can change by 100% or more at a given site. A few dozens or hundreds of

kilometers away the situation may be completely different, prompting herders to move. Winter rainfall can fluctuate greatly as well—in extreme years cold temperatures and high snow cover, often in combination with previous summer drought and (consequential) overgrazing, can result in *dzuud*, the Mongolian word for a mass mortality of herds that can affect most of the livestock in large areas (Nandintsetseg et al., 2018b; Middleton et al., 2014).

Due to the cold continental climate and severe winters the southern border of the Siberian permafrost is running through Mongolia: 67% of its area, including most of the steppe region, is classified as permafrost area (Tumurbaatar and Mijiddorj, 2006) with continuous, discontinuous or sporadic permafrost or at least isolated patches of it. These permafrost layers are important for the preservation of local ecosystem functions, because permafrost keeps soil moisture in upper layers accessible for roots by preventing rain from seeping into deeper soil layers. In such regions, top soils remain wet even under low annual precipitation (Ishikawa et al., 2018). While current permafrost temperatures are between 0° and –1 °C, an increase in temperatures and active layer thickness has been observed in the context of global warming (Sharkhuu et al., 2008).

Long winters, high altitudes and low precipitation are impacting Mongolian soils. Soil formation in the steppes is characterized by (1) slow processes of chemical weathering and clay formation, (2) slow biological element cycling and short annual period of biological activity, (3) soil formation at mean temperatures around zero degrees, and (4) a shallow humus layer and short soil profile (Dorzgotov, 2003; Tamura et al., 2013). In congruence with the ecological zonation of Mongolia, soil distribution changes from north to south in the following order (1) cryomorphic taiga soils in the mountain taiga, (2) Chernozems, dark Kastanozems, Derno taiga soils and forest darkcolored soils in the mountain forest-steppe, (3) Kastanozems dominate in dry-steppe, (4) brown semidesert soils in semidesert, and (5) gray-brown desert soil and extra-arid desert “borzon” soils in the desert zone (Dorzgotov, 2003; Tamura et al., 2013).

Biogeography and Ecology

Flora and Typology of Communities

A total of 3127 vascular plant species belonging to 683 genera, 112 families, 39 orders and 14 classes are recognized for the flora of Mongolia (Urgamal et al., 2014).

Mongolia's vegetation is dominated by different types of steppe ecosystems, which are part of the Palaearctic steppe biome (Wesche et al., 2016). They are of natural origin and can be classified according to Dengler et al. (2014) mostly as zonal steppes and in a few cases as arctic-alpine grasslands. These steppes have been used for mobile pastoral livestock husbandry at least since the Bronze Age. The original population densities of wild herbivores are not known, but Gorshkova and Lobanova (1972) and Abaturov (2001) suggested that at moderate grazing pressure the grazed steppe grasslands might resemble the original grassland communities existing before the wild herbivores were displaced by livestock. Therefore, it can be assumed that Mongolia's steppe ecosystems belong to those ecosystems on earth which are not much affected by anthropogenic transformation into other ecosystem types, and which still exist as near-natural vegetation despite their long-standing land use history. Strongly increasing livestock numbers since the 1990s (Lkhagvadorj et al., 2013b) have resulted in local or regional overgrazing and might cause steppe vegetation to get increasingly dissimilar from its original state (Bazha et al., 2012).

Biogeographically, Mongolia is located at the intersection between three different subkingdoms (i.e., the Boreal, Tethyan, and East Asian subkingdoms) of the Holarctic realm (Kamelin, 2010). The position at this phytogeographical transition zones creates a unique and diverse flora. According to a recent phytogeographical classification by Kamelin (2010), 10 floral provinces and 23 floral districts are completely or partly located on the territory of Mongolia (Fig. 2). Different types of steppe vegetation in a broader sense occur nearly everywhere in these phytogeographical units, except for three of the provinces (i.e., the dry Dzungarian, Alashan-Ordos, and Transaltai-Beishan floral provinces) or the respective four districts (Shargyn Gobi, Nom, North Alashan Gobi, and Transaltai Gobi) that comprise desert vegetation.

The occurrence of steppe vegetation across most of Mongolia's phytogeographical districts, reflecting the wide range of climate types and soil conditions, corresponds to a high diversity of steppe formations and a considerable species turnover between the different vegetation types. The major zonal grassland types basically follow a gradient of decreasing precipitation and increasing potential evaporation from north to south, including mountain meadow and meadow steppes in the north, typical and dry steppes at intermediate positions of the gradient, and desert steppes in the south (Table 2 and Fig. 3). In addition to the zonal grassland types at medium elevation, mountain steppes and alpine steppes are found in high mountain systems (Table 2).

The most productive grassland formations are montane meadow steppes, which intermingle with forests in the forest-steppe ecotone (Fig. 3A). While the moistest sites in the forest steppe support boreal forests of Siberian larch (*Larix sibirica*) and other conifers (or birch, *Betula platyphylla* at disturbed sites), the drier parts of the landscape are dominated by meadow steppes and (at climatically and edaphically more extreme sites) mountain steppes (Dulamsuren, 2004). This setting results in a vegetation mosaic of forests on north-facing slopes and grasslands on south-facing slopes and in dry valleys (Hilbig, 1995). The plains of eastern Mongolia receive relatively high amounts precipitation and thus are covered with tall grass steppes (Fig. 3C), which is floristically different from the meadow mountain steppe of the forest-steppe ecotone. Central and western Mongolia receive less precipitation and are covered by vast grasslands of typical and dry steppes. The typical steppes mark the moister sites; therefore, the typical steppe follows the meadow and mountain meadow steppes along the moisture gradient from north to south. The dry steppes receive less precipitation and thus occur south of the typical steppe. In large typical steppe areas of eastern and central Mongolia, the feather grass *Stipa baicalensis* is dominant alone or together with *S. krylovii* (Fig. 3D). In the dry steppe, the former species increasingly loses

Table 2 Main steppe types of Mongolia and selected characteristic plant species.

Steppe type	Characteristic species
<i>Zonal vegetation of lower elevations</i>	
Meadow steppe	<i>Stipa baicalensis</i> , <i>Allium senescens</i> , <i>Filifolium sibirica</i> , <i>Stellera chamaejasme</i>
Typical steppe	<i>Leymus chinensis</i> , <i>Stipa baicalensis</i> , <i>S. krylovii</i> , <i>Agropyron cristatum</i>
Dry steppe	<i>Stipa krylovii</i> , <i>Cleistogenes squarrosa</i> , <i>Koeleria cristata</i> , <i>Carex duriuscula</i> , <i>Caragana microphylla</i> , <i>C. stenophylla</i>
Desert steppe	<i>Stipa glareosa</i> , <i>S. gobica</i> , <i>A. polyrhizum</i> , <i>A. mongolicum</i> , <i>Caragana korshinskii</i> , <i>C. pygmaea</i>
<i>Steppes of high mountains</i>	
Alpine steppe	<i>Kobresia</i> sp., <i>Carex macrogyna</i> , <i>C. stenocarpa</i> , <i>C. orbicularis</i>
Montane meadow steppe	<i>Festuca sibirica</i> , <i>Stipa sibirica</i> , <i>S. grandis</i> , <i>Koeleria macrantha</i> , <i>Carex pediformis</i> , <i>Helictotrichon schellianum</i> , <i>Thalictrum petaloideum</i>
Mountain steppe	<i>Carex korshinskyi</i> , <i>Poa attenuata</i> , <i>Festuca lenensis</i> , <i>Potentilla sericea</i> , <i>Thymus gobicus</i> , <i>Artemisia commutata</i> , <i>Alyssum lenense</i>

ground with increasing aridity, whereas *S. krylovii* and *Cleistogenes squarrosa* become dominant components of the vegetation. The dry steppes of western Mongolia share the occurrence of *Stipa krylovii* and *Cleistogenes squarrosa* with dry steppes of eastern Mongolia, but additionally comprise species with western distribution ranges, like *Stipa capillata*, *S. sareptana*, and *S. orientalis*. *Stipa klemenzi*, which is another characteristic feather grass of the dry steppes in western Mongolia, is regularly associated with shrubs of different *Caragana* species (Grubov, 1963).

Desert steppes form the transition between dry steppes and the Gobi desert. The gradient from meadow to desert steppes parallels a gradient of decreasing productivity and biomass, and is associated with an increasing share of xerophytic species in the vegetation from north to south. The desert steppes are widely dominated by *Stipa glareosa* and *S. gobica* (Tuvshintogtokh, 2014; von Wehrden et al., 2009). Mongolia's desert steppes are usually a mixture of grasslands and shrublands, including, for instance, *Artemisia xerophytica*-*Stipa glareosa* or *Caragana bungei*-*Stipa glareosa* communities in western Mongolia (Grubov, 1963). Some species of onions (*Allium mongolicum* and *A. polyrhizum*) are also characteristic members of the desert steppe flora (Fig. 3E).

The boreal floral subkingdom of the Holarctic realm occurs with four floral provinces in Mongolia. Three of them (all belonging to different floral regions) only extend with small proportions of their total areas onto Mongolia's territory; this applies to the Altai-Sayan, Baikal-Dzhugdzhur, and Altai-Dzhungar provinces (Kamelin, 2010). The dominant grassland formations of the Altai-Sayan and Baikal-Dzhugdzhur provinces include alpine steppe, montane meadow steppe and mountain steppe with continental

Fig. 3 Steppe types in Mongolia from north to south. (A) Forest steppe, a mosaic of forest and meadow steppe, with forests restricted to the north-facing mountain slopes, Ulaan-Azargana, Onon river. (B) *Oxytropis*-meadow steppe in the northern Mongolian Khuvsugul district. (C) Meadow steppe in eastern Mongolia. (D) Typical steppe in eastern Mongolia, with *Stipa* grasses. (E) Desert steppe with flowering *Allium*. (F) Desert steppe in Dornogovi province. Photos (A,C,D, and F) photographed by Nyamsuren Batsaikhan, photos (B and E) by Shukherdorj Baasanmunkh.

mountain and high mountain species (e.g., *Carex orbicularis*, *C. ledebouriana*, *Aster alpinus*, and *Festuca lenensis*). This floral element has strong ties to the flora of other mountain systems of the central Siberian-Dahurian flora, which includes the flora of the Altai, Sayan and the Transbaikalian mountains.

The Tuvan-Mongolian province constitutes the fourth boreal floral province of Mongolia; it is largely restricted to Mongolia's territory with only small parts extending northward into Russia in Tuva and the south-eastern part of the Russian Altai. The Tuvan-Mongolian floral province covers large parts of western Mongolia and is highly diverse from the biogeographical point of view. Floristically, the steppes of the western part of Tuvan-Mongolian floral province share the virtual lack of East Asian plant species as common character. Different types of mountain steppes are found at high elevations in both the forest steppe and the desert steppe. The flora and vegetation of these mountain steppes is further diversified by the marked elevation profiles of the Altai, Kharkhiraa, Khan-Khuhii and Khangai mountains (Beket, 2009). Alpine steppes are dominated by *Carex* and the closely related (and nowadays often included) *Kobresia* in the Tuvan-Mongolian province. In the north-westernmost part of this floral province in Mongolia, in the Mongolian Altai, the alpine steppes are more species-rich, since plant species which are more widely distributed in the Russian Altai (e.g., *Deschampsia koeleroides* and *Oxytropis altaica*) enrich the vegetation. By contrast, the mountain steppes in the

Tuvan-Mongolian province are characterized by the occurrence of species from the Tien Shan Mountains. These steppes differ in their flora from the dry steppes and desert steppes of the plains between the mountain systems. Subdominant species include the dwarf-shrubs *Anabasis brevifolia* and *Chenopodium frutescens*; the latter is subendemic to western and north-western parts of the Tuvan-Mongolian province as well as Tuva and the Russian Altai. Furthermore, numerous species of the Dzungarian-Turanian floral element occur in the Tuvan-Mongolian desert steppes, including *Carex soongorica*, *Londesia eriantha*, *Arnebia decumbens*, *Eremostachys molucelloides*, *Asperula humifusa*, and *Serratula alata* (Grubov, 1963).

In the Khangai Mountains, an altitudinal zonation of steppe types up to the alpine belt is found. Mountain steppes represent the most common grassland type of the Khangai Mountains with, for example, *Koeleria cristata*, *Festuca lenensis*, *Poa attenuata*, *Oxytropis filiformis*, *Arenaria capillaris*, and *Potentilla sericea*. The steppe flora in the eastern part of the Khangai Mountains is more strongly influenced by the central and partly even by the eastern Mongolian flora, whereas the flora of the western Khangai Mountains is more influenced by the western Mongolian flora element.

The East Asian floral subkingdom is formed by the Dahurian-Mongolian-Manchurian and the Khalkh-East Mongolian provinces. It occupies large parts of eastern Mongolia. The borders of the East Asian floral subkingdom are primarily determined by the western distribution limits of plant species with Dahurian-Mongolian-Manchurian and Dahurian-Manchurian-North Chinese distribution ranges, or more rarely by species with an East Siberian-North-East Asian distribution (Kamelin, 2010). The East Asian floral element distinguishes the Mongolian steppes from the grasslands west of the Altai in Kazakhstan, southern Russia and eastern Europe, where precipitation is more or less evenly distributed over the year. By contrast, the Mongolian climate is characterized by a marked peak of precipitation in summer. East Asian plant species are also absent from the steppes of western Mongolia as well as from the country's southern, south-western, and south-eastern desert steppe regions. In central Mongolia, the East Asian floral element is still present, but thins out westward. The restriction of the East Asian floral element to East and Central Asia, sporadically also to central and eastern Siberia, can only be explained by the seasonal precipitation patterns. The share of the summer months (June to August) in the total annual precipitation amounts to 80–95% in Mongolia east of 100°E, 35% west of 100°E in the Depression of the Great Lakes, 40–60% in the Mongolian Altai, and 25% in Dzungaria. Species with wide distribution ranges across the entire Eurasian steppe belt (e.g., *Koeleria gracilis*) need to be highly plastic to deal with the contrasting water relations in the eastern and western parts of the steppe region.

The Khalkh-East Mongolian floral province comprises the meadow steppes and typical steppes of central and eastern Mongolia and extends into north-eastern China. The flora is formed by elements of typical, dry, and desert steppes. In the East Asian floral subkingdom, the landscape is dominated by vast plains with zonal meadow, typical, and dry steppes. This contrasts with the more mountainous western and southern parts of Mongolia. Montane meadow steppes and few mountain steppes occur in the north and desert steppes in the south of this subkingdom. In the large steppe landscapes of eastern Mongolia, a sequence of different feather grasses is found along the moisture gradient from the mountain meadow and meadow steppes in the north (with *Stipa sibirica*, *S. grandis*, and *S. baicalensis*), over the typical steppe (*S. baicalensis*, *S. krylovii*) and the dry steppe (*S. krylovii*) to the desert steppe (*S. gobica*). The steppes of eastern Mongolia are characterized by the occurrence of Dahurian-Mongolian and Manchurian-Mongolian floral elements. Examples from meadow steppes for these floral elements include *Filifolium sibiricum*, *Hemerocallis minor*, *Iris dichotoma*, and *Thalictrum squarrosum* (Dmitriev and Jargalsaikhan, 2018). Usually, the vegetation of the eastern Mongolian steppes is formed by several codominant species, such as *Stipa krylovii*, *S. grandis*, *Cleistogenes squarrosa*, *Leymus chinensis*, *Poa attenuata* subsp. *botryoides*, and *Koeleria cristata* in the dry steppe (Dmitriev and Jargalsaikhan, 2018). A further characteristic feature of the eastern Mongolian steppes is the occurrence of several *Allium* species, which can reach high cover values. *Allium senescens* is typically found in meadow steppes, *A. anisopodium*, *A. ramosum* in typical and dry steppes and *A. polyrrhizum* and *A. mongolicum* in desert steppes. *Allium bidentatum* is typical of both dry and desert steppes.

The Tethyan floral subkingdom is represented in Mongolia by four provinces. Three of them, however, are only found in the Gobi Desert and lack steppe vegetation. The fourth one, the North-eastern Gobi province, is partly covered with desert steppe, which is characterized by the occurrence of *Stipa gobica*, *Allium mongolicum*, and *Asparagus gobicus*.

Apart from mere grassland communities where grasses and herbs are mixed in different ratios, shrub-rich steppe communities are a characteristic feature of Mongolia's vegetation (Yunatov, 1950; Karamysheva and Khamtsov, 1995). *Caragana* and *Artemisia* are two genera of high significance, which contribute as shrubs (*Caragana*) or dwarf shrubs (*Artemisia*) to the steppe vegetation. Mountain steppes are the habitat of *Spiraea aquilegifolia*, *Armeniaca sibirica*, *Amygdalus mongolica*, *Amygdalus pedunculata*, *Potentilla fruticosa*, *Ribes diacanthum*, *Grossularia acicularis* and species of *Rosa*, *Cotoneaster*, and *Salix*. The dwarf shrub *Artemisia frigida* is found in mountain steppes as well as typical and dry steppes. *Caragana* plays an important role in typical, dry, and desert steppes. The typical and dry steppes of central and eastern Mongolia host *Caragana microphylla* and *C. stenophylla*, which often occur as subdominant species (Ogureeva et al., 2009). Characteristic *Caragana* species of Mongolia's desert steppes include *C. leucophloea*, *C. pygmaea*, and *C. korshinskii*. Other typical shrub and half-shrubs of the desert steppe are *Anabasis brevifolia*, *Salsola passerina*, *Kalidium gracile*, and *Reaumuria soongorica*, the latter typically occurring on saline soils.

Like in other parts of the world, high livestock densities were observed to increase the shrub cover to the disadvantage of grasses and herbs (Bazha et al., 2012). The dwarf shrubs *Artemisia frigida* and *A. adamsii* are typical examples that increase in degraded steppes. Another disturbance indicator are high proportions of *Carex duriscula* in the vegetation. The share of *Allium polyrrhizum* in the vegetation has increased, whereas that of *Stipa* and other grasses has decreased in the dry steppes of southern central Mongolia as the result of increasing aridity and increased livestock densities (Gunin et al., 2010).

Mongolia's ultracontinental climate with its dry winters has no parallels with other places on earth. Therefore, neophytes only play a small role in the Mongolian flora. Even the ruderal and segetal flora is thus formed by native species (e.g., *Chenopodium album*, *Axyris hybrida*).

Fauna

Mongolia's fauna includes 138 mammal species, 417 species of resident bird, 75 fish species, 22 reptile species, 6 amphibian species, 516 mollusk species and probably over 13,000 insect species (Batbold et al., 2015, Sundev and Leahy, 2019).

Mongolian steppes, however, are dominated by large herds of domestic livestock tended by the traditional nomads (Fig. 4A). The cultural origins of dairy pastoralism in the region date back to the Late Bronze Age ~2900–3300 years ago (Orlando, 2018). Nomadic animal husbandry has been the dominant form of agriculture all over Mongolia for thousands of years, and has continued even during the age of communistic economy.

Fig. 4 Fauna of the Mongolian steppes. (A) Mongolian steppes are dominated by the herds of the nomads. (B) A herd of Mongolian gazelles roams the steppe in Toson Khulstai, northern Kherlen River basin. (C) A wild ass or khulan, in southern Mongolia. (D) A mountain weasel *Mustela altaica*—preparing to hunt small mammals, Degree River valley, eastern Mongolia. (E) Two corsac foxes *Vulpes corsac* in mountain steppe at the northern slope of Bogd Khan mountain. (F) Demoiselle cranes (*Anthropoides virgo*) are frequent inhabitants of the Mongolian steppe. Photo (A) by M. Pfeiffer, photos (B–F) by N. Batsaikhan.

Despite this immense ecological impact, steppes and rangelands of Mongolia are still home to large herds of freely migratory ungulates (Batsaikhan et al., 2014; Mallon and Jiang, 2009). Ten species or subspecies of large ungulate herbivores live in the steppes and drylands of Mongolia, many of them highly threatened (Table 3) due to hunting, habitat change and diseases.

Mongolian gazelles (*Procapra gutturosa*) are estimated at still over 1 million animals that roam through the Daurian steppe in eastern Mongolia (Fig. 4B) (Batsaikhan et al., 2014; Olson et al., 2009). The Mongolian goitered gazelle (*Gazella subgutturosa hillieriana*) is under severe pressure from poachers who wiped out all the large herds and reduced numbers by 50% (IUCN, 2017), yet large populations survived in the Gobi and in the Eastern Mongolian steppes. The Mongolian saiga (*Saiga tatarica mongolica*) underwent a harsh genetic bottleneck: only 200 individuals had been left due to poaching in 1977, but due to active conservation and favorable climate the population increased to 11,000 in 2016. However, the population declined again when the majority of the population died in an outbreak of peste de petits ruminants (PPR, or Ovine rinderpest) that struck livestock in western Mongolia. Currently, only 3750 mature individuals are left (IUCN, 2018).

The Mongolian khulan or wild ass (*Equus hemionus hemionus*), which is ranging through southern Mongolia, lost 75% of its former habitat and is nowadays mainly restricted to the most arid areas of the Gobi (Fig. 4C) (Lkhagvasuren et al., 2018). The population is viable and stable with over 40,000 mature individuals (Buuveibaatar et al., 2017; Kaczensky et al., 2015).

Przewalski's horses (*Equus przewalskii*) are related to a horse lineage herded by the eneolithic Botai culture in northern Kazakhstan about 5500 years ago (Gaunitz et al., 2018), and are only weakly related to the modern domestic horse (Gaunitz et al., 2018) that is still of unknown origin (Fages et al., 2019). They are an enigmatic species of national importance for Mongolia. In cooperation with European zoos, *E. przewalskii* has been reintroduced to the steppes since 1992 after almost 50 years of being extinct in the wild, and still occurs only as managed populations in conservation areas (Kaczensky et al., 2003).

The argali (*Ovis ammon*), the mountain sheep, is confined to steep, jagged habitats, similar to the Siberian ibex (*Capra sibirica*), a wild goat inhabiting arid mountain areas over 1000 m a.s.l. The lower mountain forest steppe is home to red deer (*Cervus elaphus*) and wild boar (*Sus scrofa*).

Burrowing small mammals are keystone species in the Mongolian grasslands with a remarkably species diversity and abundance (Fig. 4D) (Samiya and Mühlenberg, 2006). Many species, e.g., the lagomorph pikas (*Ochotona pallasi*), are eco-engineers that increase the diversity and heterogeneity of their habitats and impact ecosystem services, e.g., by improvement of water drainage and soil fertility, establishment of new habitats for plants and provision of dens and prey for other animals (Wesche et al., 2007). Burrowing species are also most of the 64 species of rodents that are documented for Mongolia (Batsaikhan et al., 2010). These include ground squirrels (*Spermophilus* spp.), chipmunks (*Tamias* spp.), zokors (*Myospalax* spp.), hamsters (*Phodopus* spp.), dwarf hamsters (*Cricetulus* spp.), marmots, lemmings and voles that all are abundant in the grasslands. Being exceptional in that sense, most species of gerbils (*Meriones* spp.) and jerboas (*Allactaga* spp.) prefer more arid areas. The Siberian marmot (*Marmota sibirica*) is a widespread dweller in steppe, although its conservation status is "endangered" as marmots are hunted for their meat and fur, despite their status as nationally protected. Marmot burrows are often also used by corsac foxes that take advantage from the burrowing activities of these large rodents (Murdoch et al., 2009). Together with a variety of small mammals, marmots represent natural reservoirs for the plague, a vector-borne disease caused by the Gram-negative bacterium *Yersinia pestis* that is transmitted by fleas to local hunters. The main vector is the marmot flea (*Oropsylla silantiewi*), causing yearly outbreaks of the disease in rural Mongolia (Galdan et al., 2010).

Some rodents, such as the Brandt's vole (*Lasiopodomys brandti*), undergo extreme population fluctuations and can compete with livestock for food at high densities. Their cyclical rapid population growth, which increases pasture degradation, is often triggered by overgrazing (Zhang et al., 2003).

The top predators in the Mongolian steppes are wolf (*Canis lupus*), Eurasian lynx (*Lynx lynx*), bear (*Ursus* spp.) and snow leopard (*Panthera uncia*), all of them are endangered by (illegal) hunting. Especially wolves and snow leopard are under pressure as their attacks on livestock can cause considerable economical losses to herder communities and often result in reactive or preventive killing (Mijiddorj et al., 2018). Red fox (*Vulpes vulpes*) and Corsac fox (*Vulpes corsac*), as well as martens (*Martes* spp.) and other Mustelidae are among the small carnivores of the grasslands (Fig. 4E).

Table 3 Main species of wild ungulates in Mongolian steppes and arid lands, and their regional Red List status (species level) according to IUCN (2016, 2017, 2018).

Species	Scientific name	Family	Regional Red List status
Siberian Ibex	<i>Capra sibirica</i> (Pallas, 1776)	Bovidae	Least Concern (LC)
Mongolian Goitered Gazelle	<i>Gazella subgutturosa hillieriana</i> Heude, 1894	Bovidae	Vulnerable (VU)
Altai Argali	<i>Ovis ammon ammon</i> (Linnaeus, 1758)	Bovidae	Near Threatened (NT)
Gobi Argali	<i>Ovis ammon darwini</i> Przewalski, 1883	Bovidae	Near Threatened (NT)
Mongolian Gazelle	<i>Procapra gutturosa</i> (Pallas, 1777)	Bovidae	Least Concern (LC)
Mongolian Saiga	<i>Saiga borealis mongolica</i> Bannikov, 1946	Bovidae	Endangered (EN)
Red Deer	<i>Cervus elaphus</i> Linnaeus, 1758	Cervidae	Least Concern (LC)
Przewalski's Horse	<i>Equus (equus) przewalskii</i> Poliakov, 1881	Equidae	Endangered (EN)
Mongolian Kulan	<i>Equus (asinus) hemionus hemionus</i> Pallas, 1775	Equidae	Near Threatened (NT)
Wild Boar	<i>Sus scrofa nigripes</i> Blanford, 1875	Suidae	Near Threatened (NT)

Birds of prey also benefit from the abundant rodents in the steppes (Gombobaatar et al., 2009); these include upland buzzard (*Buteo hemilasius*), steppe eagle (*Aquila nipalensis*), common kestrel (*Falco tinnunculus*) and saker falcon (*Falco cherrug*), as well as owls (*Athene* spp., *Asio* spp.). Lacking roosting or perching sites in steppe areas force raptors to utilize electricity distribution pole lines, resulting in high electrocution risk (Ganbold et al., 2018). Black vultures (*Aegypius monachus*) feed on carrion of wild and native ungulates. A famous group of steppe birds are cranes (*Grus* spp.; Fig. 4F) and pheasants, as well as larks (Alaudidae) that have a high species richness and abundance in steppe environments (Wesche et al., 2016). In spring and autumn, a rich diversity of migrant birds crosses the steppes. The Mongolian bird fauna, including all residents, migrants, and vagrants, comprises 503 species (Sundev and Leahy, 2019) with diversity peaking in forest steppe and around the great lakes that are internationally important wetlands protecting threatened species and migratory waterfowls (e.g., the white-headed duck *Oxyura leucocephala*) (Sundev and Leahy, 2019).

Amphibians are rare in the steppes due to the dry climate; only six species of two orders are known for the country. They distribute along open waters and are under pressure due to the drying of surface water points (Terbish et al., 2013). Four of these species are listed as vulnerable in the red list, e.g., the Siberian salamander (*Salamandrella keyserlingii*) (Batbold et al., 2014). Two species of snakes, namely Halys (Pit) viper (*Gloydius halys*) and steppe's rat snake (*Elaphe dione*) are widely distributed over Mongolia, while *Vipera* species are mainly restricted to the mountain areas. Generally, reptiles are more common in the Gobi area.

Mongolia's steppe zone comprises a variety of lakes and rivers that include some of the least impacted freshwater ecosystems on the planet (Karthe et al., 2017). They are home to a rich fish fauna including the Siberian taimen (*Hucho taimen*), the sharp-snouted lenok (*Brachymystax lenok*), and the Baikal grayling (*Thymallus baicalensis*). These species live in sympatry throughout the country's two major river basins and are targets of a quickly growing recreational fishery (Kaus et al., 2019).

Mongolia is home to a rich insect fauna (Bayartogtokh et al., 2016). Ants (Formicinae) are abundant everywhere and important as predators and eco-engineers (Bayartogtokh et al., 2014; Pfeiffer et al., 2003). Darkling beetles (Tenebrionidae) are exceptional rich in species and well adapted to the dry climate; their radiation is strongly shaped by the steep climate gradient that provides a north-south zonation for this thermophilic taxon (Paknia et al., 2013). Copronecrophagous dung beetles (Scarabaeinae) are essential for the recycling of cattle droppings and expanded their populations in response to livestock domestication in Mongolia, as demonstrated for the telecoprid beetle *Gymnopleurus mopsus* (Kang et al., 2018). Overgrazing by cattle can impact diversity and species composition of invertebrate herbivores, e.g. moths, that compete with vertebrate grazers (Enkhtur et al., 2017). Similarly, fly communities change in their species composition and decrease in diversity in response to overgrazing (Clement et al., 2018).

Bacteria

A recent study on diversity of soil bacteria in the semi-arid steppe region of central Mongolia yield highly diverse bacterial communities dominated by the phyla or classes Bacteroidetes, Acidobacteria, Alphaproteobacteria, and others (Kim et al., 2013). Diversity in this study was closely linked to soil texture and was—presumably due to extreme climatic conditions—much higher than the diversity of comparative samples from tropical Malaysia.

Threats of Changing Land Use and Climate

Nomadic pastoralism has been the by far most important form of land use over millennia, and has changed remarkably little up to the present. Meat and milk have always been provided by sheep, goat and cattle in the moister parts, and by yaks in the cooler regions, while camel and horses have been the main animals kept for transport until very recently. Typically, herders have moved several times per year in search of fresh forage, and only winter camps were used for longer periods of time (Lkhagvadorj et al., 2013b). There were modifications to this basic scheme (Fernández-Giménez, 1999), and the advent of socialist economy resulted in herds becoming state-owned. The rangelands, in contrast, have never been under formal ownerships of private households. Livelihoods did not change fundamentally, and livestock numbers have also been stable over most of the 20th century, fluctuating between 20 and 30 million animals from the 1920s to the 1990s (Lkhagvadorj et al., 2013b). Livestock numbers varied in response to droughts and snow disasters.

In 1992, after the breakdown of socialism, livestock was privatized and since then the number of domestic animals in Mongolia has more than doubled. It was almost 66.5 million by 2018 (National Statistics Office of Mongolia, <https://www.en.nso.mn/>), including 30.5 million sheep, 27 million goats, 4.3 million cattle, 3.9 million horses and about 460.000 camels. Growth was brought about by a two to threefold increase in small livestock sheep and cashmere goats (von Wehrden et al., 2015), the latter reared for the international market. Numbers of larger livestock were stable, camels did even decline, but taken together, animal numbers converted to the standard Mongolian livestock units rose from 80 Mio. in the 1990s to over 120 Mio. today (Pfeiffer et al., 2018).

Recent rates of change were, however, very uneven across the country, and were also accompanied by changes in livelihoods. Herds increasingly concentrate in the central parts of the country around the major cities, especially Ulaanbaatar. There, but also elsewhere in the country mobility declined, with herders staying more and longer near larger settlements or at other sites with favorable infrastructure (Fernández-Giménez et al., 2017). In consequence, rangelands are increasingly degraded in the central parts of the country (Bazha et al., 2012; Hilker et al., 2014) and overgrazing has become a major problem, leading to a higher vulnerability of herds to mass mortality during dzuud (Nandintsetseg et al., 2018a) and impacting fauna and flora (Oyuntsetseg

et al., 2019). For other, especially the drier parts of the country, resampling studies and grazing experiments show mixed results with respect to grazing degradation in steppes (Khishigbayar et al., 2015; Wesche et al., 2010). Based on monitoring data collected at 1516 long-term monitoring sites all over Mongolia in 2016, about 42% of the sites were non-degraded, 14% slightly degraded, 21% moderately degraded, 13% heavily degraded and 10% in fully degraded state, while the degree of degradation of the two most heavily degraded levels has increased since 2014 by about 4% and 6%, respectively (Densambuu et al., 2018).

In comparison to grazing, other land use types have more spatially limited effects. Arable farming is practiced on <1% of the area (John et al., 2018). After large-scale fallowing in the 1990s, farming has now intensified again, but that still remains on a low level with basically local effects.

In terms of total land directly affected, large-scale mining is at a similar order of magnitude as arable farming. Effects of resource extraction extend, however, far beyond the extraction sites (Batbayar et al., 2015). In addition to mining areas, oil fields cover increasingly large regions, especially in the east. Apart from direct impact, the associated infrastructural development, especially with respect to development of traffic lines, dissects and thus affects huge parts of the steppe (Batsaikhan et al., 2014). Effects are even more pronounced as proper road infrastructure is still missing in most parts of Mongolia, where mainly unpaved roads interconnect the country. Increasing traffic, open terrain and communal land tenure have created a web of dirt track corridors, sometimes up to 4 km width, concentrating around the villages and river crossings (Keshkamat et al., 2013). Dirt tracks promote desertification by impacting plant life, facilitating erosion, soil compaction and increasing water run off; heavy dust problems may occur in mining areas with intensive traffic (Jackson, 2015). Fragmentation is the key problem here, as roads and railroads as well as settlement building have already disrupted migration patterns of Eastern Mongolia's remaining large gazelle herds (Olson et al., 2011) and wild asses (Ito et al., 2013).

Fragmentation thus adds to the direct pressure exerted by livestock herding. The high dietary diversity of sheep and goats and their overlap with wild species (Retzer et al., 2006) render increasing livestock numbers a potential risk for the survival of wild ungulates (Sugimoto et al., 2018). Recent land use changes thus have started to affect the Mongolian steppes. Not surprisingly, effects differ across the vast and environmentally heterogeneous rangelands. Grazing, as the spatially most relevant impact, interacts with climate (Liu et al., 2013), and grazing effects tend to be more pronounced in moister and thus more productive regions (Khishigbayar et al., 2015; Wesche et al., 2010). In that sense, climate change may not only have direct effects, but also indirect effects via land use change.

Climate is the overwhelmingly dominant control over most of Mongolia's ecosystems, and thus ecosystems are particularly sensitive to climate change. The highly continental climate results in relatively rapid changes, which have immediate effects on the "open-air" land use system of nomadic pastoralism (Lkhagvadorj et al., 2013a). The vulnerability of pastoralism is aggravated by the lack of stables and the scarcity of external forages sources such as hay or concentrated feed. Global warming is more intensive in Mongolia than in many other parts of the world, with the annual average temperature having increased by 2.2 °C (or 0.3 °C decade⁻¹) between 1940 and 2008 (Batbold et al., 2014). Rise of air temperature in the permafrost region in Mongolia from 1901 to 2014 has been higher than in other permafrost regions of the world, with a trend of 0.18 °C decade⁻¹, while in the period 1979–2014 temperatures rose even at a rate of 0.31 °C decade⁻¹ (Guo et al., 2018). These results have been corroborated by extensive tree ring analyses, which suggest that warming in the recent years exceeds any other time since 931 C.E. (Davi et al., 2015). Strongly rising temperatures affect permafrost and glaciers in Mongolia (Walther et al., 2017). Glacier area has decreased by 28% in the past 70 years, snowmelt occurs around 1 month earlier, and evaporation of surface water has increased largely (Batbold et al., 2014). Moreover, climate change has led to reductions in the productivity, vitality and regeneration of conifers and birch trees in Mongolia's boreal forests, which occur in close neighborhood to steppe grasslands in the forest steppe (Dulamsuren et al., 2010a,b; Liu et al., 2013; Khansaritoreh et al., 2017). Increasing dryness may also increase the probability of wild fires that impact forests and grassland, especially in eastern Mongolia (Nasanbat and Lkhamjav, 2016).

The high natural variability of precipitation in both space and time renders analysis of trends difficult, because potential long-term changes at scales of mm year⁻¹ are dwarfed by interannual variability (Pfeiffer et al., 2018). This makes statistical derivation of trends very difficult and for many stations no clear trend is discernible. Geographical factors such as the pronounced relief make modeling of large-scale climate a difficult task, and climate models show limited congruence with respect to future changes. Moreover, timing of precipitation in terms of seasonality is even more difficult to model, yet is crucial for ecosystem functioning. Shifts in the onset of precipitation can have direct effects on growing season length, and several authors described a shift from summer to spring or winter precipitation (Dagvadorj et al., 2009). Whether this will result in increased snow cover and more frequent Dzuud disasters (Middleton et al., 2014), or in higher moisture availability in spring and thus longer growing season is not clear yet. Even the locally apparent trend towards fewer but more intense rain events (Nandintsetseg and Shinoda, 2013) may prove beneficial for the drier grasslands, that often benefit less from modest rain events with respect to productivity (Heisler-White et al., 2009) or recruitment (Gunin et al., 2003; Ronnenberg et al., 2008).

Net effects of climate change are thus not easily derived and will certainly differ across the vast and diverse region of Mongolia. Aridity indices showed a decreasing tendency for the period of 1961–2015, especially in central and north east Mongolia (Nyamtseren et al., 2018; Batbold et al., 2014; Tao et al., 2015). While Mongolia has a very low number of river stations, river discharge showed a sharp decreasing trend at all stations since 1995 (Dorjsuren et al., 2018). As mining operations in Mongolia are increasing, especially underground water use is likely to increase. Similarly, the ever-growing number of livestock adds pressure on water resources.

Attributed to climate change 551 rivers, 483 lakes and 1587 springs/wells dried up in 2011 (Batbold et al., 2014). However, given the high intra-annual and interannual variations in precipitation in arid areas, long term data were needed to draw reliable

conclusions and to avoid misinterpretation of seasonal changes. Based on all available Landsat images of the Mongolian plateau from 1991 to 2017, a recent study revealed a significant decrease in area and numbers of lakes $>1 \text{ km}^2$ until 2009, followed by a partly recovery until 2013 and a further decrease in current years (Zhou et al., 2019). Rising grazing intensity could be identified as a driver of lake shrinkage in Mongolia in the first period ($r^2 = 0.45$), while rainfall had a positive effect on lake numbers and area in the second period. Altogether between 1991 and 2013 lake numbers decreased from 338 to 257 and total area of lakes $>1 \text{ km}^2$ decreased by 355 km^2 (2.6%). (Zhou et al., 2019). Earlier studies corroborated the total decline of lakes on the Mongolian plateau (Tao et al., 2015; Zhang et al., 2017).

Remote sensing studies on primary productivity are not fully conclusive. A decrease in NDVI due to decreasing precipitation and increase of temperature has been reported for the period from 1982 to 2016 (Filei et al., 2018), yet a number of previous studies showed high spatial differences or failed to find evidence for widespread decline of plant productivity (Sternberg et al., 2015; Fernández-Giménez et al., 2017).

Conservation, Restoration and Sustainable Management

In terms of sheer numbers, Mongolia perhaps has of the most well developed system of protected areas across the Eurasian steppes. The country prides itself to host one of the oldest reserves of all, the Bogd Uul range south of Ulaanbaatar being essentially in place since the late 18th century (Banzragch, 1998). After large scale gazetting in the last two decades, there are currently 99 special state protected areas covering $272,000 \text{ km}^2$ area or 17.4% of Mongolia's territory, including important steppe areas. Besides the state protected areas, there are 911 locally protected areas altogether occupying 10.3% of total territory (Batbold et al., 2015). Hustai National Park hosts the world's most viable populations of wild horses and is a role model in terms of conservation effectiveness, mediation of land use conflicts and ecotourism development (Wit and Vegten, 1998; Tserendulam et al., 2018). Formerly neglected, the Ikh Nart reserve in southeastern Mongolia has also become a well functioning reserve (Reading et al., 2016). Most other parks are far less effective, partly owing to their sheer size with reserves like Great Gobi A or Gobi Gurvan Saykhan covering $25,000 \text{ km}^2$ or even more. Many of these larger reserves are, however, situated in the country's drylands, where climate constraints limit human impact and result in relatively pristine dry steppes still occurring.

Given that larger-scale degradation is a relatively recent phenomenon in Mongolia, steppe restoration has so far not been a major topic. While the literature on grassland and dryland restoration in China is vast (e.g., Akiyama and Kawamura, 2007; Hao et al., 2014), specific restoration studies on Mongolia are lacking. There are, however, studies on population ecology of key plant species that are relevant in this context. Reproduction and germination ecology have been studied for keystone feather grass species of steppes and desert steppes in Mongolia (Ronnenberg et al., 2008, 2011). Persistence is mainly by vegetative tillering within grass bunches, while reseeding is rare and takes place in exceptional years with e.g., high-intensity rainfall events. On average, seedling establishment occurs at intervals of some decades in key grasses, and may even need centuries in woody chenopods such as saxaul (Gunin et al., 2003). Annual species germinate more easily (Ronnenberg et al., 2007; Wesche et al., 2006) and similar experiences have been made in neighboring China (Akiyama and Kawamura, 2007). Yet, the overwhelming number of key species in intact steppes is perennial, and prospects for restoration of natural vegetation types are thus at best uncertain. Clearly, restoration should be an ultimate response only, and the focus should lie on sustainable management preventing degradation and destruction of habitats.

Improved grazing management may be a pathway for recovery of highly degraded pastures. Since 2011 Mongolian government, NGOs, herders and local authorities cooperate to implement a new comprehensive approach called *resilience-based rangeland management* in order to sustain rangeland health (Densambuu et al., 2018). A nationwide network of 1516 long-term monitoring sites and 4200 photo monitoring sites has been established for rangeland assessment according to core indicators (biomass, plant height, species composition, etc.). A central database serves as platform for decision making on rotational grazing, fodder preparation, animal breeding, animal health and quality management as well as product marketing. By 2018, $>15,000$ herder families using 16 million hectare pasture land have already been organized in 740 Pasture User Groups (PUGs) by the condition of Rangeland Use Agreements (RUAs) that enforce community-led grazing schedules and herd management plans, including stocking rates adjustments (Densambuu et al., 2018). They agree to achieve a resilient carrying capacity of the grasslands and a sustainable pastoral production that is needed for food security in Mongolia and the future of its nomadic lifestyles under climate change conditions.

Acknowledgments

We thank Dr. Sci. O.P. Kamelina for her permission to use a map from an article by her late husband Rudolf Vladimirovich Kamelin. We thank Mr. Batsaikhan, N. senior lecturer at the Department of Biology, School of Arts and Sciences, National University of Mongolia, Mongolia, and Mr. Baasanmunkh, Sh. Ph.D. student at the Department of Biology & Chemistry, Changwon National University in South Korea for providing photographs for this book chapter.

Abstract

The grasslands in China cover 3.26 million km², 86% of which are the “Northern Grasslands” in the Palearctic realm, occurring primarily on the (Inner) Mongolia Plateau, the Loess Plateau and the Tibetan Plateau, and in the within-desert mountain areas in northwestern China. Vast steppes, including meadow steppes, typical steppes, desert steppes and alpine steppes, as well as alpine meadows are the zonal grassland types. Typical meadows and marshy meadows occur in azonal and extrazonal habitats on mountains and lowlands, and secondary grasslands grow in relatively humid areas in both temperate and tropical regions. The Northern Grasslands are rich in plant species and host large herds of emblematic freely migrating ungulates. These grasslands are predominantly in intact natural conditions. Grassland regions represent not only rangelands or pastures for animal production, but also are “green barriers” and “water towers,” critically important for the ecological security of Asia. These grasslands are under the threats of increasingly strong human activities such as overgrazing, conversion, collecting, hunting, open pit mining, development of infrastructures (fences, traffic lines), grassland fragmentation, as well as climate change. Distinguishing between the main grassland regions, implementing different land-use policies in these regions, and increasing the mobility and flexibility of wildlife and livestock are keys for the conservation and sustainable use of these grasslands.

Delimitation and Physiogeography

The temperate grasslands on the Eurasian continent are characterized by a vast range, mainly extending across longitudes from west to east. There is, however, a southwesterly turn at the eastern end in China. The conspicuous turning starts at the southern edge of the Mongolian Plateau and extends across the entire Loess Plateau and throughout the Qinghai-Tibet (QT) Plateau, spanning 23.8 degrees of latitude from 28° to 51.8°N (Li et al., 1980a). The hydrothermal conditions within the range of temperate grasslands in China are semi-arid to semi-humid, as the changes in thermal and moisture conditions imposed by the southward shifts are counteracted largely by the rise in relief. The temperate grassland region in China is divided into two distinct biogeographic regions, that is, the temperate steppe region and the alpine vegetation region (Wu, 1980). The temperate steppe region encompasses the large continuous blocks of the Song-Liao Plains (mostly between 120 and 500 m a.s.l.) in northeastern China, the Inner Mongolian Plateau and the Loess Plateau (mostly between 800 and 2000 m a.s.l.) in northern China, and the extensive mountain areas (mostly between 600 and 2200 m a.s.l.) in northwestern China. The alpine vegetation region mainly occupies the QT Plateau with an altitude mostly above 4000 m a.s.l. (Li et al., 1980a) (Fig. 1).

Fig. 1 Grassland biomes in China, derived primarily from “Vegetation Regionalization Map of China (1:6,000,000)” (Zhang, 2007). The zones marked as temperate mountain grasslands are actually vegetation complex with various steppes and meadows in different elevation zones, and admixed with other vegetation types. The grasslands with small or noncontinuous distribution areas, either steppes or meadows in mountainous areas or low lands, or secondary grasslands in forest regions are not shown.

The eastern Eurasian steppe region is primarily controlled by the Mongolian high-pressure anticyclone system during the winter, thus being cold, dry and windy. Yet, these steppes are also influenced by the southeasterly maritime monsoonal system in summer, when conditions are warm and relatively humid. The mean annual temperature ranges from -3 to 5°C depending on locality, with the coldest and warmest month means from -7 to -29°C (January) and 18 to 26°C (July), respectively. The annual precipitation varies mostly between 200 and 500 mm; inter-annual variability is pronounced, and about 70% of rains fall in the plant growing season, beneficial to plant growth (Li et al., 1980b). Temperate grassland soils are of several types (Li et al., 1980b). The black soil, Chernozem soil, Chestnut soil and brown soil are sequentially distributed along a gradient of increasing climatic aridity from south-east to northwest on the Inner Mongolian Plateau, or on the mountains from low to high altitudes in the arid regions in Xinjiang. The black soil occurs mainly in the piedmont hilly plains, being rich in organic matter, and has a pH of 5.6 – 6.6 but no calcium accumulation, and supports forb meadows. The Chernozem, Chestnut and brown soils have a pH ranging from 7.5 to 9.5 , an organic matter content from 6% to 1% in top soil layer, and calcium accumulation at depths from 70 to 25 cm in soil profile. These are soils support meadow steppes, typical steppes and desert steppes (Li et al., 1980b).

The alpine steppes and meadows occur dominantly on the QT Plateau, which is under a typical plateau continental climate characterized by humid summers controlled by the South Asian and East Asian monsoons and cold and dry winters influenced by the Westerlies and the Siberian High (An et al., 2001). Patterns in mean annual temperatures are more directly controlled by topography; most areas have an annual mean from -5.8 to 3.7°C , and the means of the coldest and warmest months range from -17 to -8.0°C and 5.5 to 13.6°C , respectively. The alpine grasslands include the vast continuous steppes in the north and the west, and the meadows or scrubby meadows in the south and the east, reflecting a decreasing precipitation gradient from southeast (above 400 mm) to northwest (below 100 mm; Wang et al., 1980a). The water systems on the QT Plateau comprise both exterior and interior ones. Exterior rivers are primarily in the wide marginal areas, being the headwater and upper reaches of several big rivers in China and Southern Asia, such as Yangtze River, Yellow River, Lancang River (Mekong River in Southeast Asia), Yarlung Zangbo River (Brahmaputra-Jamuna Rivers in India and Bangladesh) and Gar Zangbo River (Indus River in Kashmir and Pakistan). The interior rivers flow into lakes of various sizes in the central part of the QT Plateau, most of which are salty due to the intense water evaporation under the arid continental climate. Alpine steppe soils are variants of the temperate steppe soils on the

Inner Mongolian Plateau, having developed under cold conditions from a high diversity and variety of substrates and associated geomorphologic processes. Leptic Cambisols and Leptosols occur mainly on steep upper slopes, while Gleysols are often found close to rivers or lakes. Alpine meadow soils are mainly Gelic Gleysols, Gelic Cambisols and Permagelic/Gelic Histosols (Baumann et al., 2009). They are rich in organic matter and their surface layer is full of compact root networks resulting in a high resilience against mechanical disturbance.

The Chinese grasslands in the Palearctic realm cover 2.82 million km², including temperate steppes at 0.75 million km², alpine steppes at 0.58 million km² and alpine meadows at 0.64 million km². Mountain and lowland meadows extent over 0.42 million km², secondary grasslands over 0.18 million km², and other scattered grasslands over 0.25 million km² in azonal and extrazonal habitats (Ministry of Agriculture, 2006). The grasslands in southern China cover 0.45 million km² including small areas of savanna. The grassland distribution is well presented in the vegetation map of China (Edition Board of Vegetation Map of China, 2007) and the maps of the Terrestrial Ecoregions of the World (TEOW; Olson et al., 2001; Pfeiffer et al., 2018).

Biogeography and Ecology

The temperate steppe region in China, along with that of Mongolia, constitutes the eastern most part of the Eurasian steppe zono-biome, and the majority of the steppe region belongs to the Central Asian steppe subzonobiome (Li et al., 1980a). However, the most northwestern part of the steppe region in the western Altay Mts. and the Tarbagatay Mts. as well as their piedmont sloping plains, is delimited as a separate “Western steppe sub-region” in “Vegetation Regions of China” (Li et al., 1980a), and considered as the easternmost part of the Black Sea-Kazakhstan steppe subzonobiome, as the steppes in this sub-region contain characteristic species of Kazakh steppes, such as *Stipa sareptana* and *S. kirghisarum*. The grasslands on the QT Plateau, including alpine steppes and meadows, are delimited as one alpine vegetation region (Wang et al., 1980a). The alpine steppes are distributed across the larger part of the QT Plateau, and are connected to the steppes on the Loess Plateau and the Mongolian Plateau, whereas the alpine meadows occur mainly on the southeastern parts, typically above 4000 m a.s.l.

Flora

Incomplete statistics show that some 4100 vascular plants can be found in the temperate steppe region, which are affiliated to ca. 800 genera and 140 families (Li, 1995). Phytogeographically, the region belongs to the Tethys Sea floristic realm (Wu and Wang, 1983; Li, 1995). The Central Asian steppe species, especially the Mongolian ones, are most prevalent in the flora, especially in the typical and desert steppes. The meadow steppes in the Northeast China plains also have many temperate Asian species.

The QT Plateau vegetation region has a very rich, diverse and often endemic flora. It comprises species of Central Asian (semi-) deserts, as well as temperate East Asian and Himalayan elements. The dominant herbaceous species are not typically grasses, but are frequently sedges of genera *Kobresia* and *Carex*, especially in alpine and subalpine meadows. Recent studies (Global Carex Group, 2015) suggest that the genus *Kobresia* should be included into *Carex*, but here we still keep the traditional nomenclature to allow comparison to most of the relevant literature. A total of 5766 plant species have been documented for the Tibetan Autonomous Region (Wu, 1983; Li, 1995). More than 2000 of these species are recorded for the grassland region, of which 86% are forage plants and occur mainly in the humid and sub-humid pastures of eastern Tibet, while 540 species occur in the arid and semi-arid rangelands (Gu, 2000). The flora of alpine steppes consists of Eurasian steppe species (*Festuca kryloviana*, *F. pseudovina*, *Stipa glareosa*, *S. krylovii*, *S. bungaena*), as well as Central Asian alpine (*S. subsessiliflora*), Pamir-QT Plateau (*S. purpurea*, *S. roborowskyi*, *F. olgae*, *Carex moorcroftii*), and QT Plateau endemics (*S. subsessiliflora* var. *basiplumosa*, *S. capillacea*; Wang et al., 1980a).

Fauna

The faunal diversity in the temperate grassland region in China (and Mongolia) was recently reviewed by Pfeiffer et al. (2018). The temperate steppes and arid lands in Inner Mongolia, QT Plateau and Xinjiang host large herds of freely migrating ungulates (Mallon and Jiang, 2009), including 12 species of large herbivores, emblematic of different rangeland systems in the region (Fig. 2). Mongolian gazelle (*Procapra gutturosa*), Mongolian Saiga (*Saiga tatarica mongolica*), goitered gazelle (*Gazella subgutturosa*), Mongolian argali (*Ovis ammon*), Asian wild ass (*Equus hemionus*), Asiatic ibex (*Capra sibirica*), wild camel (*Camelus ferus*), and Przewalski's horse (*Equus przewalskii*) occur mostly on the temperate steppes and nearby arid lands. Several unique mammals are found in Tibetan steppes, such as Tibetan antelope (*Pantholops hodgsonii*), Tibetan gazelle (*Procapra picticaudata*), Przewalski's gazelle (*Procapra przewalskii*), Tibetan wild ass (*Equus kiang*) and wild yak (*Bos mutus*). Some species prefer mountain habitats, e.g., white-lipped deer (*Cervus albir-ostriis*), blue sheep (*Pseudois nayaaur*) and Tibetan argali (*Ovis ammon hodgsoni*). The majority of these ungulates are threatened migratory species. Przewalski's horses have recently been reintroduced in Xinjiang after they had been extinct in the wild for decades (Mallon and Jiang, 2009; Pfeiffer et al., 2018).

Small herbivorous mammals on the steppes include marmots (*Marmota bobak*), ground squirrels (*Spermophilus* spp.), hares (*Lepus* spp.), plateau pikas (*Ochotona* spp.), voles (*Microtus* spp.) and Zokors (*Myospalax baileyi*). The burrowing of these herbivores has profound effects on the patterns and processes of grassland ecosystems (Wesche et al., 2007). Small carnivores include Tibetan steppe foxes (*Vulpes ferrilata*), red foxes (*Vulpes vulpes*), martens (*Martes* spp.), while the top predators are wolves (*Canis lupus*), lynx (*Lynx lynx*), bears (*Ursus* spp.) and snow leopards (*Panthera uncia*) (Pfeiffer et al., 2018).

Fig. 2 Typical wild animals on Tibetan grasslands. (A) Tibetan wild ass (*Equus kiang*); (B) Tibetan steppe fox (*Vulpes ferrilata*); (C) Tibetan gazelle (*Procapra picticaudata*); (D) Tibetan antelope (*Pantholops hodgsonii*); (E) black-necked crane (*Grus nigricollis*); and (F) Plateau pika (*Ochotona curzoniae*). Photos credit: J. Schmidt and Huaben Duo.

Steppe eagles (*Aquila nipalensis*) and Saker falcons (*Falco cherrug*) are threatened avian raptors, while Cinereous vultures (*Aegypius monachus*) live on carrion of ungulates on the steppes. Larks (*Alaudidae* spp.) are the dominant birds with high species richness and abundance (Wesche et al., 2016). Other bird species include upland buzzards (*Buteo hemilasius*), goshawks (*Accipiter gentilis*), black kites (*Milvus migrans*) and some waterfowl, such as black-necked cranes (*Grus nigricollis*), bar-headed geese (*Anser indicus*) and ruddy shelducks (*Tadorna ferruginea*). The steppes are also rich in invertebrates including grasshoppers (*Orthoptera*), moths and butterflies (*Lepidoptera*), ants (*Formicinae*), and ground-dwelling beetles (*Coleoptera*), which play an important role in grassland ecosystem functioning (Pfeiffer et al., 2018).

Origin of the Grasslands

Much of the contemporary natural grassland region in China was covered by subtropical forests and savanna woodlands during the Tertiary period. The grasslands formed as a consequence of the region getting drier with the uplift of the QT Plateau since the Tertiary, especially after the repeated glacial periods in the Quaternary, during which the region became progressively arid and continental (Dinesman et al., 1989; Pfeiffer et al., 2018). This led to the gradual development of xerophilous steppes replacing the former mesophilous vegetation. Thus, the flora is relatively young in the region, though certain older relict species can still be found (Li et al., 1980a).

The extensive natural steppes and high-altitude grasslands have been grazed over evolutionary time-scales as proven by the rich native grassland fauna. Human land use dates back to the early Holocene, when hunter-gatherers roamed the grassland region. Nomadic pastoralism has expanded on the Mongolian Plateau since the Bronze Age, yet livestock keeping left major imprints on the dry steppes of the Mongolian Plateau not earlier than 900–600 years ago (Dinesman et al., 1989; Pfeiffer et al., 2018). The impact of human activities has dramatically increased over the last decades; some temperate meadows or steppe meadows have been converted into cultivated lands (Wu et al., 2015), and some grazing land has been seriously degraded. Yet, the temperate steppes are still in relatively intact conditions.

The evolutionary history of biodiversity and endemism on the QT Plateau is still under debate, depending on differing hypotheses on highland uplift and climate history. Similarly, the history and intensity of human impact on Tibetan grasslands are under discussion based on evidence from diverse disciplines (Miehe et al., 2019). The most recent proposal suggests that long-term

residential groups of hunters, probably early pastoralists, had settled in this region between 8 and 5 ka BP, which is supported by genomic evidence from yak domestication (Qiu et al., 2015). However, as a consequence of increased animal husbandry and fires, forests had undoubtedly disappeared although the climate conditions were relatively favorable for their development.

Typology of Plant Communities

The natural grasslands in China are classified into temperate grasslands, including temperate steppes and meadows, and alpine grasslands including alpine steppes and meadows (Wu, 1980; Guo et al., 2018). There are also secondary grasslands in the humid and semi-humid temperate regions, and secondary grasslands and savannas in the humid or dry tropical and subtropical regions. We present mainly the temperate and alpine grasslands of the Palearctic realm in this article, but also briefly describe those of tropical and subtropical regions.

The temperate steppes (Fig. 3) include meadow steppes, typical steppes and desert steppes, which are mainly distributed on the Inner Mongolian Plateau and the northern and western part of the Loess Plateau spreading from east to west along a gradient of climatic aridity, and on the uplifted zones on the within-desert mountains in Xinjiang region. Alpine steppes are found mostly on the QT Plateau (Li et al., 1980b; Sun, 2005; Kang et al., 2007).

Meadow steppes occur on relatively moist and fertile sites among the temperate grassland habitat, typically in areas with annual precipitation around 450 mm and soils of high organic content. The dominant species are mostly mesoxerophilous, xeromesophilous or pan-xerophilous (i.e., adapted to a relatively moist part of dry habitats, or relatively dry condition of medium moist habitats, or a wide range of dry habitats), including the bunchgrasses *Stipa baicalensis*, *S. kirghisorum*, *Cleistogenes mucronata*, *Bothriochloa ischaemum*, *Pennisetum flaccidum*; the rhizomatous grasses *Leymus chinensis* and *L. angustus*; and forbs such as *Filifolium sibiricum*. Meadow steppes usually lack dwarf semi-shrub species.

Fig. 3 Main grassland types on the Mongolian Plateau. (A) desert steppe dominated by *Stipa klemenzii*; (B) typical steppe dominated by *Stipa krylovii*; (C) typical steppe dominated by *Stipa grandis*; (D) meadow steppe dominated by *Leymus chinensis* and *Achnatherum sibiricum*; (E) meadow steppe dominated by *Leymus chinensis* with diverse forbs (*Iris dichotoma* in the front); (F) meadows dominated by *Sanguisorba officinalis* and *Bromus inermis*; (G) Przewalski's horses reintroduced on the steppe; (H) a pastoral household on the steppe; (I) degraded grassland dominated by *Artemisia frigida* and *Potentilla acaulis*. The photos (A)–(F) were taken along a climate gradient from dry to humid regions; and photos (G)–(I) were taken in the typical steppe region. Photo credit: F.Y. Li.

Typical steppes occur under a semi-arid climate with annual precipitation around 350 mm. Plant species are typically drought-tolerant. The most common communities are dominated by bunchgrasses such as *Stipa grandis*, *S. krylovii*, *S. bungeana*, *S. capillata*, *Festuca sulcata*, *F. ovina*, *Cleistogenes squarrosa*, *Agropyron cristatum*, *Koeleria cristata*, *Poa botryoides* and *Aristida trisetia*, and semi-shrubs and dwarf semi-shrubs, such as *Artemisia frigida* and *Thymus mongolicus*.

Desert steppes occur under the most arid and continental climate, with annual precipitation between 150 and 250 mm. The species are predominantly strongly xerophilous grasses, usually accompanied by super-xerophilous dwarf semi-shrubs in large numbers. The common dominant species include the bunchgrasses *Stipa klemenzi*, *S. gobica*, *S. breviflora*, *S. glareosa*, *S. orientalis*, *S. caucasica*, *Cleistogenes songorica*, rhizomatous forbs like *Allium polyrrhizum*, and the dwarf semi-shrubs *Ajanina achilloides*, *Hippolytia trifida* and *Artemisia dalailamae*.

Alpine steppes are mostly found at elevation between 3300 and 5300 m a.s.l. on the QT Plateau. The common dominant species are extremely cold- and drought-tolerant grasses and dwarf shrubs, with a more or less pronounced admixture of cushion plants. The dominants include locally distributed species such as *Stipa subsessiliflora* var. *basiplumosa*, *S. roborowskyi*, *Festuca olgae*, *Carex moorcroftii*, *Orinus thoroldii* and *O. kokonorica* and *Artemisia salsoloides* var. *wellbyi*; yet there also are common plants of Eurasian steppes such as *Festuca kryloviana* and *F. pseudovina*.

Meadows in classic European understanding are agriculturally managed grasslands regularly mown for livestock forage (UNESCO classification; Ellenberg and Mueller-Dombois, 1965/1966). In China, meadow refers to natural grasslands primarily composed of mesophilous perennial herbs that thrive under moderate moisture conditions. The meadows naturally occupy vast continuous areas with moderate moisture conditions that derive from atmospheric precipitation, and with relatively low temperature that limits the growth of trees, such as alpine meadows on the QT Plateau. However, in most other cases meadows are azonal, occurring in the montane, alpine, plain and coastal areas of the temperate zones, with moisture originating from groundwater, runoff, or melted snow and ice; these meadows are classified into typical, marshy and salt meadows, based on the ecological traits of their constituent species, that is, the dominance of mesophilous, xero-mesophilous, hygro-mesophilous or halo-mesophilous species in their composition (Wang et al., 1980a, b).

Alpine meadows occur mainly on the eastern QT Plateau (Fig. 4) and in part on the high mountains of northwestern China and northern China, under an alpine cold climate with intermediate humidity, adequate sunshine, intense solar radiance, and strong

Fig. 4 Main grassland types on the QT Plateau. (A) moist alpine meadows dominated by *Kobresia setschwanensis* and *Polygonum macrophyllum* (the white flowers) in Maqu, Gansu province; (B) winter pastures dominated by *K. royleana* and *K. pygmaea* in Yushu, Qinghai province; (C) moist alpine meadows in Dangxiong, central Tibet; (D) alpine meadows dominated by *K. pygmaea* in Namco, central Tibet; (E) alpine steppe dominated by *Stipa purpurea* in Qumahe, Qinghai province; (F) alpine steppe dominated by *Orinus thoroldii* in Gaize, western Tibet; (G) alpine marshy meadow dominated by *K. schoenoides* in Linzhou, eastern Tibet; (H) large root/shoot ratio from *K. pygmaea* turf; (I) newly built winter settlements from sedentarization project in Qinghai province. winds. Here the word “alpine” does not strictly refer to mountain climate, which is not warm enough to allow for tree growth, but only indicates high-elevation distribution. Alpine meadow soils are shaped by intense sod-forming processes during pedogenesis, and are characterized by the occurrence of semi-decomposed residual turf, closely-interwoven root mats, and a poorly-intermingled humus layer. The *Kobresia* alpine meadows are the most typical and most widespread of the alpine meadows in China. *Kobresia* species are both mesophilous and cold- and drought-tolerant. There are about 40 *Kobresia* species, dominant ones include *K. pygmaea*, *K. humilis*, *K. capillifolia*, *K. graminifolia*, *K. setchuanensis*, *K. prattii*, *K. royleana*, *K. smirnovii* and *K. bellardii*. There are also alpine meadows dominated by typical sedges such as *Carex scabriostriis*, *Blysmus sinocompressus*, bunchgrasses such as *Festuca ovina*, *Poa alpina*, *Anthoxanthum odoratum*, and forbs such as *Polygonum viviparum*, *P. sphaerostachyum*, *Ligularia virgaurea* and *Alchemilla japonica*.

Typical meadows occur mainly in the temperate forest and steppe regions, and on the high mountains of the desert and subtropical forest regions. They are particularly abundant in ecotone areas from the forest to the steppe regions, or in subalpine belts of high mountains, usually in or above the forest belt and on black soils. They are primarily dependent on precipitation, and dominated by mesophilous forbs. Typical meadows also occur at low-lying sites of valleys and river plains that are controlled by groundwater and dominated by grasses. The dominant meadow species include forbs *Sanguisorba officinalis*, *Phlomis alpina*, *Iris ruthenica*, *Medicago falcata*, *Melilotus albus* and *Trifolium repens*; the rhizomatous grasses *Calamagrostis epigejos*, *Bromus inermis*, *Brachypodium* spp., *Hierochloa glabra*, *Agrostis mongolicus*, *A. alba*, and *Elytrigia repens*; the bunchgrasses *Dactylis glomerata*, *Trisetum sibiricum*, *Deyeuxia arundinacea* and *Elymus nutans*; and the sedge *Carex stenophylla*.

Marshy meadows are primarily composed of hygrophilous herbs and have transitional characteristics between a typical meadow and a marsh. Their occurrence is generally associated with high soil moisture regulated by special topographic factors, most often at poorly drained sites, thus with humid and poorly-aerated soil. The existence of a permafrost layer is also a major cause for association of humid soil conditions and marshy meadows, such as on the QT Plateau. Massive layers of humus and even peat or a semi-peat layer accumulate in soils of marshy meadows due to slow decomposition of plant residuals. Examples of alpine marshy meadows include those dominated by *Kobresia tibetica* along streams or waterlogged areas over permafrost in the catchments of the Yellow River, Yangtze, Mekong and Salween. *Kobresia schoenoides* is, however, dominant along the Yarlung Zangbo River. *Carex schmidtii* or *Sanguisorba parviflora* dominate at the river flats adjacent to forest stands in Hinggan Mts.

Saline meadows are mainly composed of mesic perennial halophytes, that is, salt-tolerant or otherwise adapted species, and occur on salinized low-lying sites, wide valleys, fringes of lake basins and river flats within steppe and desert regions. Most widely distributed saline meadows include those dominated by *Achnatherum splendens*, *Leymus dasystachys*, *Phragmites communis*, *Sophora alopecuroides*, *Crypsis aculeata* and *Suaeda* spp.

Secondary grasslands occur mainly in warmer, southern or south-eastern forest regions. They are in the serial succession stages of original forest vegetation under disturbance, such as the temperate grasslands dominated by *Bothriochloa ischaemum* and *Themeda japonica*, with or without admixtures of shrubs such as *Vitex negundo* var. *heterophylla* or *Ziziphus jujuba* in northern China, and the tropical and subtropical grasslands dominated by *Miscanthus sinensis* in southern China.

Savannas in tropical and subtropical China are primarily confined to the dry and hot valleys in Yunnan province where the *Heteropogon contortus*, *Woodfordia fruticosa* and the *Bombax malabarica* community occur, to the seashores of Guangdong province, and on the basaltic plain in the northern portion of the Hainan Island, such as the *Heteropogon contortus*, *Flacourtia indica* and *Streblus asper* community. The savannas are mostly secondary in nature, thus having a noncontinuous, scattered distribution range.

Biodiversity Patterns

The temperate steppes border with the Gobi deserts at the dry end, and the temperate forests at the humid end. The steppe plants, especially dominant *Stipa* species, have xeric structural traits such as reduced leaf area, leaf involution, stomatal subsidence, and well-developed root system. Many plants (e.g., *Stipa*, *Festuca* and *Allium*) form dense clumps with shoot bases being thickly clothed by persistent dead leaf sheaths to avoid overheating of the ground in summer and to protect regenerative buds in winter (Li et al., 1980b).

Plant species richness and biomass production increases with the climatic humidity from desert steppes via typical steppes to meadow steppes (Li et al., 1994; Bai et al., 2009). The species density surveyed using nested quadrats increases from 8 species on 1 m², 12 species on 16 m² and 16 species on 256 m² in desert steppe sites with precipitation around 150 mm, via 14 species on 1 m², 21 species on 16 m² and 29 species on 256 m² in typical steppe sites with precipitation around 350 mm, to 20 species on 1 m², 32 species on 16 m² and 42 species on 256 m² at meadow steppe sites with precipitation around 500 mm (Fig. 5A). The density recorded in these 1-m² quadrats is similar to that reported by Ma and Fang (2006) for the Inner Mongolian steppes, that is, 10 (range 4–23), 12 (5–25) and 20 (10–35) species on 1 m² for desert steppes, typical steppes and meadow steppes, respectively based on a survey at 207 sites. The ecological turnover of steppe species of the same genera is very pronounced along the climate gradient, especially for the genera *Stipa* (Fig. 5B), *Astragalus* and *Caragana*, and the same holds true for *Kobresia* species (Zhang et al., 1995).

The species richness of alpine, semi-arid steppes is similar to that of temperate, semi-arid steppes. Alpine meadows are generally more diverse than steppes, having 45, 35 and 23 species in average for the communities dominated *Kobresia pygmaea*, *K. humilis* and *K. tibetica* (marshy), respectively, recorded in 20 quadrats of 0.5 m² in a survey at representative sites of these alpine meadows in the northeastern QT Plateau (Wang et al., 1999).

Fig. 5 (A) Species density of desert steppes, typical steppes and meadow steppes recorded using nested quadrats of 0.125 to 256 m². The values are the averages of 18, 18 and 13 nested quadrats respectively for the desert steppes, typical steppes and meadow steppes. Ecosystem Services and Threats

The temperate and alpine grasslands in China are still relatively intact in structure. The grassland ecosystems have been traditionally used as grazing land by nomadic herders for animal production. Regulating ecological services such as prevention of wind erosion and sand fixation, conservation of water and soil resources, carbon sequestration, biodiversity conservation, as well as cultural services such as ecotourism, have received increasingly attention during the past three decades. The temperate steppe regions in Inner Mongolia and Xinjiang are recognized as a major “green barrier” for ecological security, with major importance for prevention of wind erosion and reduction of dust storms in northern China. The alpine grassland region on the QT Plateau is another “green barrier” for ecological security of China. The area in the eastern part of the QT Plateau harbors the headwaters of three major rivers (Yellow, Yangzi, and Lancang) in Asia, and is considered as the Asian “water tower.” The Three River Headwater National Park, with an area of 123,100 km², has been gazetted for conservation purpose (NDFC [National Development and Reform Commission of China], 2018). Ecological health of these grassland ecosystems is critically important not only for a sustainable pastoral society in these regions but also for the ecological security of whole China and beyond. The shift of the grassland administration from the Ministry of Agriculture to the National Forestry and Grassland Ministration (under the Ministry of Natural Resources) in 2018 also indicates a shift of the government’s primary goal for grassland management, from animal husbandry production to ecological services. The total values of ecosystem products and services for human welfare and sustainable development, in terms of Global Ecosystem Products (GEP), has been crudely estimated in China (Ouyang et al., 2016). A recent estimate of the GEP for Inner Mongolia suggests that only 7% of its total GEP is from product provision, and 76% is from ecological regulation (Inner Mongolia Academy of Agriculture and Animal Husbandry, unpublished report, 2019), indicating the important role of grasslands in terms of ecological services. New estimates based on an intensive field survey shows that the grasslands in China contains 25.4 Pg C, representing 28.3% of the total carbon pool in China’s terrestrial ecosystems (Tang et al., 2018). Another estimate suggests that about half of the grassland carbon pool in China is in alpine grasslands (Schleuss et al., 2015). However, a series of inappropriate human activities and climate change is exerting great threats to the grasslands.

Overgrazing

The grasslands have been traditionally used as grazing land by nomadic herders. Land use has significantly changed since the 1950s through a series of government policies, including collectivization of land and livestock in 1950s and decollectivization in 1980s (*Household responsibility system*), a shift from nomadic to sedentary systems, and an increase in human population and associated livestock numbers (Thwaites et al., 1998; Ptackova, 2011; Hua and Squires, 2015; Wu et al., 2015; Li and Li, 2016). The social change induced overgrazing and, less importantly, over-mowing (Li et al., 2008; Harris, 2010; Baoyin et al., 2014), at least locally resulting in serious grassland degradation. Estimates show that about 47% of grassland areas are severely to moderately degraded in China (State Environmental Protection Administration, 2000). Grassland degradation leads to declines in plant species diversity, productivity and soil carbon storage (Li et al., 2008; Zhao et al., 2017). The current stocking rates on the Inner Mongolia grasslands are estimated to exceed its carrying capacity by 3.2 times (Briske et al., 2015). On the QT Plateau, although grasslands are also

considered widely degraded by overgrazing (most frequently quoted number is 30% of grassland estimated to be degraded), the extent and causes of degradation are still under debate (Harris, 2010). A summary of a larger number of case studies across Chinese grasslands suggests that locally increased grazing intensity indeed has negative effects on vegetation cover and aboveground biomass, but does not necessarily reduce plant species richness, while effects on soil conditions vary also among grassland types and are site-dependent (Fig. 6, Wang and Wesche, 2016). The nonconsistent grazing effects reflect abiotic interactions, particularly with precipitation. In semi-humid alpine meadows, grazing effects on vegetation are more obvious than in semi-arid steppes (Wang et al., 2017, 2018). This suggests that managing stocking rates is important in relatively stable alpine meadow systems, while developing management regimes adaptive to the highly variable environment is more important in the steppes that represent examples of nonequilibrium systems.

Fig. 6 Relative grazing effects on (A) vegetation, (B) soil indicators from different grassland types based on available studies across Chinese grasslands between 2000 and 2014 (Wang and Wesche, 2016). Error bars indicate standard deviation and numbers close to the error bars represent sample sizes. Abbreviations for grassland types: DS, desert steppe; S, steppe; ADS, alpine desert steppe; AS, alpine steppe; AM, alpine meadow; AS, alpine swamp. Abbreviation for the indicators: AGB, aboveground biomass; BGB, belowground biomass; rsRatio, root/shoot ratio; BD, soil bulk density; SOC, soil organic carbon; tN, soil total nitrogen; tP, soil total phosphorus; aP, plant available phosphorus in soils.

Land conversion

Conversion of grasslands into arable lands for crop or forage production is limited to meadow and meadow steppe areas. More than 10% of grasslands are estimated to be converted in Inner Mongolia (Wu et al., 2015), and the proportion is greater on the Loess Plateau and Northeastern China Plains. However, the extreme conditions put severe constraints on further conversion. Grasslands in the oasis in the Hexi corridor and the Junggar and Tarim basins in northwest China are largely converted, yet this land conversion is a local phenomenon in the vast grassland region. On the QT Plateau, converting land for crop production is not reasonable due to the short growing season at the generally high altitudes and under the extreme climate conditions. Tibet's only large agricultural regions are located in the central and the southern parts, along the Yarlung Zangbo River valley and also the main river valleys in western Sichuan and eastern Qinghai.

Plant Collecting and Animal Hunting

Collection of wild species, including medical and edible plants, fungi and "algae" has exerted profound effects on these species and the grassland environment. Collection of the edible cyanobacterium *Nostoc flagelliforme* has largely damaged the soil crust and induced soil erosion in desert steppe areas. Excavating the roots of various medical plants such as *Glycyrrhiza uralensis*, *Saposhnikovia divaricata* and *Bupleurum scorzoniferolium* as well as the Chinese caterpillar fungus *Ophiocordyceps sinensis* has not only markedly reduced the abundance of these species but also damaged the soils. The (illegal) hunting is still a pressure for native ungulates and small mammals, though poaching declines with the increasingly strong implementation of the laws and regulations for nature conservation.

Mining, Urbanization and Development of Infrastructure

The development of the roads and railways, the rapid expansion of open pit mining, and the fencing schemes in the course of sedentarization and privatization of land-use rights (Li and Li, 2016) lead to obvious fragmentation of Chinese grasslands (Squires and Hua, 2017), which hampers migration of wild ungulates, reduces mobility of livestock, and affects the sustainability of grassland use. The large-scale barrier formed by the fence that runs along much of the Chinese-Mongolian border has blocked the migration of wild ungulates.

Climate Change

The greatest climate warming trend was observed in the semi-arid region in China, with the climate becoming warmer and drier at an accelerated rate (Huang et al., 2015, 2019). The significant warming trend and large inter-annual variation in precipitation has started to constrain plant growth in temperate and alpine steppe grasslands, and also affects the pastoralism in natural grassland regions. This happens in spite of a slight increase in precipitation in the alpine steppe region over the past three decades (Qian et al., 2012; Haung et al., 2016). However, increased temperature and precipitation levels are generally favorable to plant growth in meadows in the QT Plateau (Haung et al., 2016). Aboveground biomass of an alpine meadow was shown to increase with increased precipitation rather than with experimental warming (Fu et al., 2018). Chen et al. (2013) reviewed the impacts of climate change and human activities on biogeochemical cycles on the QT Plateau, suggesting that warming increased net primary production as well as soil respiration, and resulted in significant permafrost thawing and glacier melting, which lead to substantially increased methane consumption of meadows. The variation and change in climate subsequently affects grassland and animal production, and financial and environmental outcomes of herders households. Thus, adaptive management must be addressed in devising policies (Smit et al., 1996). The management measures to adapt to climate variability and changes in the steppe region include selling livestock, buying forage, reserving pastures for extreme climate events, housing livestock and looking for other alternative jobs to compensate for economic losses (Hou et al., 2012). Local ecological knowledge and community-based institutions are beneficial to improve resource availability and distribution and to reduce risks caused by climate change (Fu et al., 2012).

Conservation, Restoration and Sustainable Management

A series of policies have been implemented to prevent grassland degradation and to restore degraded sites in China. Formal conservation of grasslands has been implemented by setting up a series of natural reserves or protected areas. The protected areas in the grassland region in China account for some 15% of the total area, which is higher than in other grassland regions of the world (Wesche et al., 2016). Reserves are, however, not balanced among grassland types or regions. The protected areas in Inner Mongolia account for 11.7% of the total area with typical and desert steppes being under-represented (Ma et al., 2016); while a single complex of 11 reserves on the QT Plateau accounts for 0.8 million km². Outside their typically small core zones, livestock grazing is allowed in almost all reserves in the grassland region.

Several major policies have been implemented in the grassland region with the objectives to reduce overall grazing pressure and restore the degraded grassland, including "Retire Livestock to Restore Rangeland" (RLRR; 2003), and "Ecological Subsidy and Award System" (ESAS; 2011). The latter aims to maintain the ecological services while improving herder livelihoods through providing

subsidies for the year-round “grazing-ban” area (approx. 14.0 USD per ha) or “forage-livestock balance” area (approx. 3.5 USD per ha), and through increasing subsidies for livestock production system and infrastructure improvement, as well as providing training to facilitate diversification of herders’ livelihoods (Li and Li, 2016). The large-scale application of these policies, involving fencing of rangeland, year-round or seasonal removal of grazing livestock, and encouraging pastoralists to move out from degraded rangelands among other have improved the overall health of grassland ecosystems. Especially vegetation cover has improved and thus capability of grassland to prevent soil erosion and desertification (Piao et al., 2015). Nonetheless, grassland management strategies such as fencing, grazing bans or rearing livestock in stables have been questioned from an ecological and social point of view (Li and Huntsinger, 2011; Wang et al., 2014; Hua and Squires, 2015). The fences cause a loss of flexibility and increase the vulnerability of the pastoral system to global changes, and they also block the passage of migratory ungulates. The challenge is to optimize management practices that result in “win-win” outcomes for grasslands, the environment, and households. This is possible by reducing animal numbers considerably using an energy-balance/market-based approach while improving household incomes (Kemp et al., 2013), with the “Ecological Subsidy and Award System” and other policies to foster restoration of degraded grassland. To restore mobility and flexibility of both native and livestock animals and to develop multiple ecosystem services are recommended key measures for sustainable pastoralism (Shang et al., 2014; Wang et al., 2014; Wu et al., 2015). Regional planning encompassing multiple goals of grassland management through implementation of the ecological red-line policy (Xu et al., 2018) and design of ecological corridors including those across Chinese-Mongolian borders, are recommended strategies towards conservation and sustainable use of the grasslands.

Acknowledgment

FYL and KG acknowledge support of the Inner Mongolia Department of Science and Technology for Mongolian Plateau project (201503001), the Chinese Academy of Sciences for the Strategic Priority Research program (XDA19050402) and the Chinese Ministry of Ecology and Environment for the Red List of Ecosystems project. YJ and KW acknowledge support of the German Federal Ministry of Education for the MoreStep project within the BioTip funding scheme. Thanks to Xianguo Qiao for assistance in preparation of Fig. 1.

Glossary

Chagusaba Meadows maintained by annual mowing specially for green tea production.

Houbokuchi (or maki) Pastures that have been maintained by grazing and annual burning.

Karishiki Green manure produced in *shibakusachi*. *Kari* and *shiki* mean mowing plants and spreading to fields, respectively.

Kayaba *Miscanthus* or *Phragmites* dominated meadows that have been maintained by mowing and annual burning for thatch roofing.

Kurobokudo The Japanese black soil, which indicates long history of semi-natural grassland vegetation.

Saisochi Meadows managed by mowing and burning for winter fodder production.

Satokusachi (or keihansochi) Meadow strips around paddy and vegetable fields. They have usually been managed by frequent mowing.

Shibakusachi Meadows producing green manure for paddy and crop fields.

Abstract

Natural or semi-natural grasslands and shrublands are small but widely distributed throughout Japan, although the forest vegetation is the potential climatic climax under the humid climates in the most parts of the country. Grasslands and shrublands have been formed by natural and anthropogenic disturbances and/or specific soil conditions in the Japanese archipelago. Since the last century, however, grasslands, especially semi-natural ones, have decreased in the area continuously, mostly due to land-use changes (abandonment, intensified use, afforestation and urban development) driven by socioeconomic growth in Japan. The rapid declines, along with fragmentation and degradation, of semi-natural grasslands have caused significant biodiversity loss as in the other Palaearctic regions but most of those grasslands and shrublands are not well protected. Natural grasslands and shrublands, on the other hand, have been protected from anthropogenic developments in general, but their area may decrease by climate changes in the future. The anti-disaster development, such as dams and embankments, reduced natural disturbances and have caused reduction and degradation of grasslands and shrublands in riparian and coastal areas. In some oceanic islands, feral goats have had significant negative impacts on grassland and shrubland vegetation. Some grasslands and shrublands on limestone and serpentine soils and on oceanic islands are often hotspots of endemic species whereas semi-natural, riparian and coastal grasslands harbor many plant and animal species which used to be found throughout Japan but now at high risk of extinction. Thus, in Japan, recent human activities largely degraded and reduced Japanese grasslands and shrublands which have high conservation values. To protect these invaluable ecosystems, a suite of activities have been initiated to promote biodiversity conservation and restoration in Japanese grasslands and shrublands.

Delimitation and Physiogeography of the Region

Japan is an island country located at the eastern edge of the Eurasian continent. The Japanese archipelago consists of more than 6800 islands, most of which are continental but some are oceanic, stretching c. 3000 km long from the Philippine Sea to the Sea of Okhotsk in the western Pacific Ocean region (20°25'–45°31' N, 122°56'–153°59' E). The total land area is approximately 378,000 km², and over 97% of the area are of the four main continental islands, Hokkaido, Honshu, Shikoku and Kyushu islands (Fig. 1). The terrain is mostly mountains and the highest elevation is 3776 m a.s.l. at the summit of Mt. Fuji. The current population of Japan is 126.2 million and most population is concentrated in urban areas near the coast, plains and valleys.

In Japan, the climate is strongly governed by seasonal winds (i.e., monsoon) and latitudinal extent. The climate mostly belongs to temperate (e.g., Tokyo: mean temperature 5.2 °C in January, 26.4 °C in August) but varies largely from subtropical in the south (e.g., Naha: mean temperature 17.0 °C in January, 28.9 °C, July) to subarctic in the north (e.g., Utoro: mean temperature –5.6 °C in January, 19.0 °C in August). The monsoon strongly influences precipitation patterns throughout the country. Winter monsoon brings cold and wet air from the Eurasian continent and results in heavy snows to the coastal parts of Sea of Japan, while summer monsoon and typhoon brings hot and wet air from the Pacific Ocean to the most parts of Japan, providing high annual precipitation (c. 1000–3500 mm per year) over the country (Numata, 1961). The climatic climax vegetations are a variety of forests and currently primary and secondary forests cover approximately 67% of terrestrial areas of the country (Ministry of the Environment of Japan, 2016). Meanwhile, natural grasslands and shrublands below sub-alpine zones are distributed very narrowly in the areas with wind-swept, heavy snow and/or avalanche areas, in riparian and coastal areas, in relatively small islands with high permeability and in the areas on limestone and serpentine soils and volcanic materials (Kitamura, 1956; Hayakawa, 1993; Koizumi, 1996, Fig. 1). Currently, semi-natural grasslands are distributed in very limited areas as well (Fig. 2).

Major soil types are Andsols (Japanese black soils or *kurobokudo*, c. 31% of the lands), Brawn forest soils (c. 30%) and Lowland soils (mostly alluvial soils, c. 14%) in Japan, although the estimate percentages differ depending on the soil categorization systems (Obara et al., 2016): total estimated area of Andsols used to be estimated as approximately 17% of the Japanese land surface (Ushimaru et al., 2018). Riparian and coastal natural grasslands and shrublands establish on lowland soils or Sandy Regosols (c. 0.7%) whereas semi-natural grasslands are distributed primarily on Andsols (Ushimaru et al., 2018). Andsols typically contain many grass phytolith and charcoal particles, indicating long historical use of semi-natural grasslands associated with fire (Kawano et al., 2012; Miyabuchi et al., 2012). In contrasts to the general rarity of Andsols (< 1% of that in the world, IUSS Working Group WRB, 2015), this soil type is very widely distributed throughout Japan but is concentrated to the montane areas of Kyushu, Shikoku and Honshu (including the foot of Mt. Fuji) as well as lowlands of Kanto plain and the south-eastern Hokkaido. Dark red soils, which are developed on limestone and serpentine bedrocks, are narrowly scattered over the montane areas of the whole country (c. < 0.5%, Obara et al., 2016). Immature soils originated from volcanic materials, serpentine and coral reefs are found in c. 7% of the land surface whereas podosols covers only 2% and are mainly found in hills and lithic plains and partly sand dunes (Obara et al., 2016).

Biogeography, Flora and Fauna

The Japanese Archipelago had begun to separate from the eastern edge of the Eurasian Continent since 20 Ma in the Miocene (Isozaki, 2019). This geological event caused the biogeographic separation of flora and fauna between the islands and the continent. Throughout the duration since this period to the present, most parts of the islands have been covered with various types of forests, although constituting flora have changed depending on climatic conditions in the geological time scale (Yabe, 2019).

During repeated glacial periods in the Quaternary, formations of land bridges led to biogeographic exchanges between the Japanese peninsulas and the mainland of the continent. Three routes on the land bridges allowed the exchanges of species: (1) the northern route through Sakhalin or the Kuril islands which connected Hokkaido and Russia, (2) the western route through the Korean Peninsula which connected Kyushu and the north-eastern China, (3) the southern route through Taiwan, Ryukyu islands which connected Kyushu and the south-eastern China (Tojo et al., 2017). Most of the present grassland and shrubland species in Japan are considered to have immigrated into this area through the northern route or the western route during the ice ages in the Quaternary. The Japanese islands and north-eastern Eurasia have lots of grassland herb and butterfly species in common at present, although multiple immigrations of these species could have occurred during the repeated glacial periods. Recent molecular phylogeographic studies partly supported the scenario (Uchida et al., 2016b; Takaishi et al., 2019). Meanwhile, subtropical island flora and fauna have been suggested to immigrate from the southern route.

In the present biogeographic regions of the world, most of the Japanese Archipelago is assigned to the Palaearctic region, whereas Ryukyu islands are assigned to the Oriental region. As a sub-division of the Palaearctic region, the Sino-Japanese region is commonly recognized in studies on the biogeography of plants (Hotta, 1974) and butterflies (Hiura, 1984; Saigusa and Araya, 2015). Majorities of plants and butterflies in the Japanese grasslands have the Shino-Japanese or the Palaearctic distributions.

Several dozens of herb and woody species in semi-natural grasslands of Japan are also distributed in the Korean Peninsula, the north-eastern China and the Russian Far East (Murata et al., 1998; Tabata, 1997; Igari, 2012). The greater part of these species inhabit Honshu and Kyushu, but not in Hokkaido. This pattern of distribution suggests the importance of the western route of immigration in the glacial periods for the grassland herbs (Murata et al., 1998). Tabata (1997) argued the possibility that these species dispersed from the continental temperate meadows which still exist at present in north-eastern China (The Editorial Board of Vegetation Map of China, Chinese Academy of Science, 2001). Similar arguments are also proposed on the immigration routes of grassland insect species including Lepidoptera, Coleoptera, Hemiptera and Orthoptera (Hiura, 1984).

The majority of the mammals of Japan mainly inhabit forests. Only a few species of mammals, such as a harvest mouse *Micromys minutus* (Palaearctic) and the Japanese grass vole *Microtus montebelli* (endemic) prefer grassland habitats, although mammals utilize both forests and grasslands include the sika deer *Cervus nippon* (Sino-Japanese), the Japanese hare *Lepus brachyurus* (endemic), the red fox *Vulpes vulpes* (Holarctic) and dozens of other species (Tsukada, 2007). The sika deer prefer to eat herb species and recently often inflict damages on biodiversity of semi-natural grasslands, even though they keep using forests as their hiding places. Japanese breed horses, constituted of several strains, are found in several locations in Japan but are considered to be descendants of populations transported by humans from Mongolia through the Korean Peninsula during the period of the 3rd–5th centuries (Nozawa et al., 1998). As of today, there is no evidence that the horse inhabited Japan during the earlier parts of the Holocene. Among 417 species of birds in Japan, 20–30 species, including the Japanese skylark *Alauda arvensis japonica* and the Chestnut-eared bunting *Emberiza fucata*, are considered to inhabit grasslands (Tojo, 2007).

Origin of the Grasslands and Shrublands

After the last glacial period (during the Holocene), the temperate and humid climate would have facilitated the succession to forest vegetation over the Japanese islands. Various natural grassland and shrubland types, however, still exist narrowly under timberlines of Japan (Figs. 1 and 3, Table 1). Natural grasslands and shrublands are maintained by heavy snow, frequent avalanches, strong winds and landslides in subarctic (subalpine) and cool temperate zones. In lowland floodplain and coastal areas, natural grasslands have been maintained by frequent natural disturbance agents, such as flooding, waves and strong winds. Some chemical and physical soil conditions, which are provided from limestone and serpentine bedrocks, can limit tree growth and often facilitate the establishment of herbs and shrubs as well (Kitamura, 1956; Hayakawa, 1993; Koizumi, 1996). In small continental and oceanic islands, such as Nansei, Oki, Izu and Bonin (Ogasawara) islands, natural grasslands and shrublands are often developed on highly jointed basalt or limestones originated from coral reefs creating high soil permeability resulted in dry soil conditions (Shimizu, 1991; Hayakawa, 1993). Around active volcanos, grasslands and shrublands are often established around solfataras and on lava flows and pyroclastic materials throughout Japan (Ministry of the Environment of Japan, 1999).

Anthropogenic activities such as burning, grazing and mowing have created and maintained various types of semi-natural grasslands in hilly and montane areas and often in lowland floodplains, coasts and small islands (Fig. 4). The beginning of Japanese semi-natural grasslands, indicated by the start of Andosols formation, may date back to c. 10,000–40,000 BP in the Aso area, Kyushu (Sakaguchi, 1987; Kawano et al., 2012; Miyabuchi et al., 2012; Hosono and Sase, 2015). Semi-natural grasslands from the Jomon period (13,000 BC–300 BC) to the Yayoi period (~250 CE) are hypothesized to have been maintained for hunting by burning, but this hypothesis has rarely been examined archeologically (Sakaguchi, 1987; Suka et al., 2012).

During the 3rd–5th centuries, pastoralism (horse and cattle grazing) was introduced to the Japanese islands from the Eurasian continent. Since then, pastures increased from the 8th to mid–19th centuries, and become widely distributed in Japanese islands (Ushimaru et al., 2018). In contrast, historical transition in meadow distributions is largely unknown in Japan, but the strong association with the development of cultivated fields has been suggested (Ogura, 2006; Mizumoto, 2015). Indeed, several types of meadow have been maintained for thatch roofing, winter fodder for livestock, and grass-compost (green manure). Until a hundred years ago, meadows were widely maintained all over the country (Ogura, 2006).

However, since the late 19th century, the semi-natural grasslands have continuously decreased in areas (only 1–3% of the national land area today) and were heavily fragmented (Ogura, 2006; Suka et al., 2012; Ushimaru et al., 2018). Some pastures

Fig. 1 Distribution map of Japanese natural grassland and shrubland vegetation. The map was drawn based on the 5th vegetation survey (1988–96) by Japanese Ministry of the Environment.

and meadows are still actively managed for husbandry or for sightseeing and tourism (Japanese Society of Grassland Science, 2010), but most remaining semi-natural grasslands have been abandoned (Nagata and Ushimaru, 2016; Uchida et al., 2016a; Koyama et al., 2017). Currently, only a small fraction of the “semi-natural” pastures have been maintained whereas some fractions were converted into artificial sown pastures: eastern Hokkaido, northeastern Honshu and Aso areas in Kyushu are the main areas of current husbandry (Ushimaru et al., 2018).

Typology of the Communities

Natural Grasslands and Shrublands

Here, we refer to grasslands and shrublands maintained or temporally established by natural disturbances and specific soil conditions as “natural grasslands and shrublands” whereas those maintained by continuous anthropogenic managements are referred as “semi-natural grasslands” (Table 1). Grasslands and shrublands established temporally or maintained continuously after land-use changes and grazing animals are called as “secondary grasslands and shrublands” in this paper. Dengler et al. (2014) classified Palaearctic grasslands into four types: steppes, Arctic-alpine grasslands, azonal and extrazonal grasslands and secondary grasslands. According to the classification, all Japanese natural grasslands (and shrublands) which are introduced in this chapter are azonal and extrazonal whereas both semi-natural and secondary grasslands (and shrublands) are included in secondary types: arctic-alpine grasslands and shrublands are outside the scope of the chapter. Because natural grasslands and shrublands are often next to each other and are maintained by similar disturbance agents in various ecosystems, we describe them together for each ecosystem. The following categorization was based on the modification of the 5th vegetation survey by Ministry of the Environment of Japan (1999).

Windswept grasslands and shrublands

From subalpine (subarctic) to cool temperate montane zones, natural grasslands and shrublands are maintained by strong winds, heavy snow, frequent avalanches and/or landslides (Fig. 1). Windswept grasslands are primarily established on the mountain

Fig. 2 Distribution map of Japanese semi-natural and secondary grassland and shrubland vegetation. The map was drawn based on the 5th vegetation survey (1988–96) by Japanese Ministry of the Environment.

summits and ridges whereas those maintained by frequent avalanches and landslides are found on steep slopes and valleys (Fig. 3A). In these grasslands, dwarf bamboos (*Sasa* spp.) are often dominant throughout the country whereas tall forbs, such as *Ranunculus acris* var. *nipponicus*, *Veratrum* and *Reynoutria* spp. are often abundant in heavy snow areas of Hokkaido and Honshu. Similarly, natural shrublands are also established due to heavy snow, frequent avalanches, strong winds, landslides and rocky environments in subalpine and cool temperate zones (Fig. 3B). In windswept and rocky shrublands, diverse shrub species (e.g., *Sorbus commixta*, *Rhododendron pentaphyllum* var. *nikoense*, *R. quinquefolium* and *Enkianthus campanulatus*) can be dominant. Meanwhile, in areas with frequent avalanches, shrublands dominated by *Weigela hortensis*, *Alnus pendula* and *Rhododendron trinerve* have been established.

Riparian grasslands and shrublands

In riparian zones, *Phragmites*-, *Miscanthus*- and annual plant-dominated grasslands and willow-dominated shrublands have been maintained by frequent flooding (Washitani, 2001; Osawa et al., 2010). *Phragmites japonicus* is a dominant grass species in upstream riparian areas whereas *P. australis* and *M. sacchariflorus* are dominant species in downstream areas. In temperate riparian areas shrublands dominated by *Salix gracilistyla* and *S. triandra* subsp. *nipponica* are maintained in up- to mid-stream and mid- to downstream, respectively, throughout the main islands (Ministry of the Environment of Japan, 1999). Grasslands on riparian levees are often managed by mowing to keep grassland landscape and sometimes harbor endangered species (Fig. 3C).

Coastal grasslands and shrublands

Because Japan is an island country with total coastal lines of over 30,000 km, several types of natural coastal grasslands and shrublands maintained by strong wind and wave disturbances and/or high salinity (Ishikawa et al., 1995) are found throughout the country. Coastal grasslands and shrublands are roughly divided into four types: those on sand dunes, cliffs, uplifted coral reefs and subtropical coastal shrublands (Figs. 3D and E). Coastal sand dune grasslands and shrublands are usually continuously (and often mixedly) distributed, such that grasslands establish in the front of coastal lines and shrublands behind them (Miyawaki, 1991). *Imperata cylindrica* var. *koenigii* (Fig. 3D) and *Carex kobomugi* and *Vitex rotundifolia* widely dominate in coastal sand dune grasslands and shrublands, respectively. In addition to these species, *Mertensia maritima* subsp. *asiatica* and *Rosa rugosa* are typical

Table 1 Grassland (GL) and shrubland (SL) types and their dominant species in Japan.

Types	Climatic zone		Factors influencing establishment	Dominant species
<i>Natural</i>				
Windswept	GL	Subalpine (subarctic)–cool temperate	Wind, snow, avalanches, landslides	<i>Sasa</i> , <i>Veratrum</i> and <i>Reynoutria</i> spp.
	SL	Cool temperate		<i>Sorbus commixta</i> , <i>Rhododendron</i> spp., <i>Weigela hortensis</i>
Riparian	GL	Temperate	Flooding	<i>Phragmites japonicus</i> , <i>P. australis</i> , <i>Miscanthus sacchariflorus</i>
	SL	Subalpine (subarctic)–temperate		<i>Salix gracilistyla</i> , <i>S. triandra</i> subsp. <i>nipponica</i>
Coastal sand dune	GL	Temperate-subtropic	Wind, high salinity, sandy soils	<i>Imperata cylindrica</i> var. <i>koenigii</i> , <i>Carex kobomugi</i>
	SL	Temperate-subtropic		<i>Rosa rugosa</i> , <i>Vitex rotundifolia</i> , <i>Juniperus chinensis</i> var. <i>procumbens</i>
Coastal cliff	GL	Temperate-subtropic	Wind, rocky soils	<i>Miscanthus condensatus</i> , <i>M. sinensis</i> , <i>Libanotis coreana</i> f. <i>ugoensis</i>
	SL	Temperate-subtropic		<i>Euonymus japonicus</i> , <i>Pittosporum tobira</i> , <i>Quercus phillyreoides</i>
Uplifted coral reef	GL	Subtropic	Lithic soil conditions	<i>Zoysia pacifica</i> , <i>Sporobolus virginicus</i> , <i>Lepturus repens</i>
	SL	Subtropic		<i>Artemisia chinensis</i>
Coastal	SL	Subtropic	High salinity	<i>Hibiscus</i> spp., <i>Scaevola taccada</i> , <i>Pandanus odoratissimus</i>
	GL and SL	Subalpine (subarctic)–temperate		Diverse depending on climatic and other conditions
Serpentine and Limestone Island	GL	Temperate–subtropic	Dry soil conditions	<i>Zoysia tenuifolia</i> , <i>Miscanthus condensatus</i>
	SL	Subtropic	Dry soil conditions	<i>Distylium lepidotum</i> , <i>Pouteria obovata</i>
Volcanic	GL and SL	Subalpine (subarctic)–subtropic	Specific soil conditions	Diverse depending on climatic and other conditions
<i>Semi-natural</i>				
Pasture	GL	Subalpine–subtropic	Grazing and/or burning	<i>Zoysia</i> spp., <i>M. sinensis</i> , <i>Pleiolablastus</i> spp.
Meadow	GL	Subalpine–subtropic	Mowing and/or burning	<i>M. sinensis</i> , <i>Sasa</i> spp., <i>Pleiolablastus</i> spp., <i>P. australis</i>
<i>Secondary</i>				
Cutoverland	GL and SL	Subalpine (subarctic)–subtropic	Clear cutting of timber	Diverse grass, forb and shrub species
Animal grazing	GL	Subalpine (subarctic)–subtropic	Wild deer or feral goat grazing	Unpalatable species, alien species

species distributed in the temperate regions and *Thuarea involute*, *Ipomoea pes-caprae* and *Scaevola taccada* are in subtropical regions. Windswept grasslands and shrublands on coastal cliffs are usually neighboring each other and often found just beside dune vegetation (Fig. 3E). Cliff grasslands are dominated by forb species, such as *Libanotis coreana* f. *ugoensis*, *Lilium maculatum*, *Cyrtomium falcatum*, *Peucedanum japonicum* var. *japonicum* as well as grasses (e.g., *Miscanthus condensatus* and *M. sinensis*) whereas shrublands are dominated by *Euonymus japonicus*, *Pittosporum tobira*, *Quercus phillyreoides* and *Eurya emarginata* both in warm temperate and subtropical zones. In subtropical island coasts, natural grassland and shrubland vegetations, which are dominated by *Zoysia pacifica*, *Sporobolus virginicus*, *Lepturus repens* and *Artemisia chinensis*, are established on uplifted coral reef-originated flat plain, plateau and cliffs. In a special case, subtropical rocky or cliff grasslands are established around seabird nesting areas in some oceanic islands. Subtropical coastal shrublands, whose dominant species are *Hibiscus hamabo*, *H. tiliaceus*, *Scaevola taccada* and/or *Pandanus odoratissimus* are often established in brackish water areas at estuaries and on sand dunes and uplifted coral reefs of southern islands.

Grasslands and shrublands on specific soil conditions

In Japan, natural grasslands and shrubland and their complex are occasionally found on dark red soils (on serpentine or limestone bedrocks), likely owing to their specific soil chemical and physical conditions (Kitamura, 1950, 1956; Hayakawa, 1993; Koizumi, 1996, Fig. 3F), as in the other Palaearctic regions (Whittaker, 1954). The species composition, sometimes containing endemic herb and shrub species that are predominantly distributed in the vegetation, usually vary depending on climatic and physiographic conditions (Kitamura, 1956, 1957; Yamanaka, 1960).

In oceanic and small continental islands, such as Bonin, Izu, Sado, Nansei, Iki and Oki islands, dry soil conditions often facilitate establishment of natural grasslands and shrublands (Shimizu, 1991; Hayakawa, 1993; Yoshida et al., 2002, Figs. 3G and H). Island natural grasslands have often been used for pastures where *Zoysia tenuifolia* and *Miscanthus condensatus* are dominant species

Fig. 4 Semi-natural and secondary grasslands and shrublands in Japan. (A) Pasture, (B) lithic grassland used as pasture, (C) *saisochi* meadow, (D) *satokuschi* meadow, (E) ski slope grassland, (F) a training ground of the Japan Self-Defense Force, (G) grassland herbs in a cutover land, (H) secondary grasslands 15 years after feral goat eradication in the Yomejima island (H). Photos by A. Ushimaru (A, D–G), Daichi Funamoto (B), Yuko K. Nagata (C) and Kazuto Kawakami (H).

(Hayakawa, 1993). Dry scrub dominated by *Distylium lepidotum* and *Pouteria obovata* is established owing to extreme dry soil conditions in summer in Bonin islands (Shimizu, 1991; Yoshida et al., 2002, Fig. 3H).

Volcanic activities have created grasslands and shrublands with relatively sparse vegetation covers around solfataras, on lava flows and on pyroclastic materials throughout Japan (Ministry of the Environment of Japan, 1999). In solfataras grasslands and shrublands, species composition often differs depending on the climatic zones (Tsujimura, 1977). Diverse plant species such as *Carex angustisquama*, *Ledum palustre* subsp. *diversipilosum* var. *nipponicum*, *Avenella flexuosa*, *Miscanthus sinensis* and *Sasa kurilensis* are often abundant in the solfataras vegetation (Tsujimura, 1977). *Rhododendron kiusianum*, *Avenella flexuosa*, *Reynoutria japonica* var. *compacta*, *Reynoutria japonica* var. *terminalis*, and *Nephrolepis cordifolia* often form sparse vegetation on lava flows. *Campanula punctata* var. *hondoensis* and *Cirsium purpuratum* constitute vegetation on denuded lands of active Mt. Fuji.

Semi-Natural Grasslands

Semi-natural grasslands are distributed from lowland to subalpine zones and can be roughly divided into pastures and meadows (Fig. 4A–D). At present, relatively wide semi-natural grasslands are distributed in the Aso-Kuju area of Kyushu, around Mt. Fuji, the center (Nagano Prefecture) and the northeastern areas of Honshu, although most semi-natural grasslands have become shrunk, fragmented and isolated (Ogura, 2006, Fig. 2). The distribution of pastures and meadows largely overlaps with the Andosol distribution (Ushimaru et al., 2018). In addition, some riparian and coastal, limestone and island grasslands (e.g., Akiyoshi-dai, Shikoku-Karst and Oki) have often been maintained as pastures and meadows by burning, grazing and/or mowing (Hayakawa, 1993; Washitani, 2001; Tsuda et al., 2002; Obata et al., 2012, Fig. 4B), although their distributions could not often be precisely distinguish in the map (Figs. 1 and 2) due to limited nation-wide information.

Pastures

Today, pastures (*hobokuchi* or *maki*, Fig. 4A and B) are distributed very narrowly within the country (such as in Toimisaki, Aso, Sanbe, Oki and Shiriya-zaki). Pastures have traditionally been managed by combining spring burning and grazing (Koyanagi et al., 2013), but currently many pastures are maintained only by grazing. *Zoysia japonica*-dominated pastures are usually found in cool-temperate (central) regions whereas those dominated by *Miscanthus sinensis* and/or *Pleiblastus* spp. are in warm-temperate (southern) regions (Numata, 1969).

Meadows

Several meadow types have been maintained for various uses in Japanese traditional rural livelihood (Ushimaru et al., 2018). *Sasa* spp., *M. sinensis* and *Pleiblastus* spp. are dominant grasses in northern, central and southern meadows, respectively (Numata, 1969). Meadows usually have higher vegetation heights than pastures and exhibited higher diversity of forbs, sometimes including many endangered species, such as *Lithospermum erythrorhizon*, *Polemonium kiusianum*, *Echinops setifer*, *Platycodon grandifloras* and *Vincetoxicum pycnostelma*.

In the past, *M. sinensis*- (or sometimes other *Miscanthus* spp.-) and *Phragmites australis*-exclusively-dominated meadows (*kayaba*) for thatch production were widely found in hilly and riparian areas, respectively, throughout the country. The meadow type is usually managed by spring burning and grass harvest during October to December. Today, due to the housing modernization, only a very small fraction of them remain in places such as in the Aso region and around Mt. Fuji.

Traditionally, stock breeders have managed meadows for winter fodder production (*saisochi*, Fig. 4C). In the mid-17th century, expansive meadows that produced green manure for rice and crop cultivated fields (*shibakusachi*) were maintained in foothills near villages (Ogura, 2006). However, the meadows of this type were mostly abandoned after the invention of chemical fertilizers in the 20th century. In the Aso region, meadows for green manure production are still actively managed but in very limited areas. These meadow types are usually commons and have been managed with both burning and mowing by local communities (Nagata and Ushimaru, 2016; Uchida et al., 2016a; Koyama et al., 2017).

In addition to the above meadow types, relatively narrow private meadows (*satokusachi* or *keihansochi*, Fig. 4D) have been maintained by individual farm families around paddy and crop fields. Around cultivated fields, belt-like meadows on levees are maintained by frequent (1–7 times per year) mowing rarely combining with spring or winter burning for insect/pathogen control as well as for fodder and green manure production in the past, but today only for keeping landscape (Uematsu et al., 2010; Uematsu and Ushimaru, 2013; Koyanagi et al., 2014; Uchida and Ushimaru, 2014). Dominant grass species of *satokusachi* meadows are known to change from *Pleiblastus* spp., *M. sinensis*, *Imperata cylindrica* var. *koenigii* to *Z. japonica* as mowing frequency increases. As paddy and other fields cover c. 18.4% of the total land area (c. 68,000 km²), the total area of this meadow type was estimated up to c. 1850 km² in 2010 (Ministry of Agriculture, Forestry and Fisheries of Japan, 2016).

Miscanthus sinensis- or *Pleiblastus chino*-dominated narrow meadows producing green manure for tea fields (*chagusaba*) have been managed to improve the tea quality in green tea production areas in Shizuoka Prefecture (Kusumoto and Inagaki, 2016). Farmers usually mow once during autumn and winter to maintain these meadows. As the ratio of *chagusaba* area to tea plantation area is estimated 0.71 in the Higashiyama district of Kakegawa city, the total area of this meadow type is considered to be significant in the tea producing areas (Kusumoto and Inagaki, 2016).

As modern land uses, ski and golf course development have maintained kinds of semi-natural grassland since the early 20th century. Ski slope grasslands are often dominated by *M. sinensis* under typical management only by annual mowing in autumn (Fig. 4E). Some ski grasslands developed on old pastures have harbored diverse endangered grassland species (Nakahama et al.,

2018; Yaida et al., 2019). Other ski grasslands developed by forest clear-cutting are dominated by introduced *Festuca rubra*, *Pteridium aquilinum* var. *latiusculum* and some woody species (Tsuyuzaki, 1995). Golf courses usually host a very low plant diversity, because the alien grasses (e.g., *Zoysia* spp.) are predominantly used, but some courses have maintained diverse grassland species just besides the courses by mowing management (Ushimaru et al., 2018). Moreover, relatively large-scale semi-natural grasslands have been maintained by spring burning as training grounds for the Japan Self-Defense Forces (Fig. 4F). These grasslands are scattered distributed within the country and share similar species compositions to meadow vegetation and host many endangered species (c.f. Ohwaki, 2018).

Secondary Grasslands and Shrublands

At cutover lands, secondary grasslands and shrublands are established and maintained for several years after clear-cutting in secondary forests and conifer plantations (Ministry of the Environment of Japan, 1999). Despite their short time periods, cutover lands are widely distributed from subalpine to warm temperate regions throughout the country (Fig. 2) and harbor many shrub, grassland herb and insect species (Inoue, 2003; Ushimaru et al., 2008). In cutover lands, *Sasa* spp., *M. sinensis*, *Cirsium* spp. *Rubus* spp., *Aralia elata* and *Stephanandra incisa*, are often abundant (Inoue, 2003, Fig. 4G).

In subalpine and temperate zones, recently increasing deer grazing has facilitated the establishment of secondary grasslands dominated by toxic plant species, such as *Senecio cannabifolius*, *Ligularia dentata* and *Hypolepis punctata*. In Bonin and Izu islands, grazing by feral goats have maintained alien herb-dominated secondary grasslands (Shimizu, 1991; Hayakawa, 1993, Fig. 4H).

Ecology and Biodiversity Patterns

For biodiversity conservation, natural and semi-natural grasslands and shrublands are essential ecosystems. Japan harbors more than 2800 endemic terrestrial plant species (including endemic subspecies and varieties) and is designated as a global biodiversity hotspot: 36% of vascular plant species are endemic to Japan (Kato and Ebihara, 2011). Grasslands and shrublands on serpentine and limestone areas (Mt. Apoi, Mt. Yubari and Mt. Shibutu) and those in oceanic (Bonin and Izu) islands are regional hotspots of endemic herb and shrub species (Ebihara, 2011). Riparian gravel bar grasslands have many river-side specialist species such as *Potentilla chinensis*, the endemic *Anaphalis margaritacea* subsp. *yedoensis*, *Artemisia capillaris*, *Eusphingonotus japonicus* and *Omophron aequalis* (Washitani, 2001; Yoshioka et al., 2010; Ministry of the Environment of Japan, 2014). Riparian grasslands often harbor non-endemic but endangered plant species as well (Fig. 4C). Coastal grassland and shrubland vegetation exhibit high endangered plant diversity: 23% of the coastal-specialist species are listed in the national red list (Sawada et al., 2006). Riparian and coastal grasslands sometimes share the same species with semi-natural grasslands.

As for Japanese semi-natural grasslands, a lower endemism in plant species composition are known: the same species are distributed in grasslands of the Korean Peninsula and meadow steppes of northeastern China (Kadota, 2011). Despite a low endemism at the species level, semi-natural grassland butterflies exhibit a higher endemism at the subspecies level (Ohwaki, 2018). Moreover, many semi-natural grassland plant and animal species are now at risk of extinction in Japan (Koyanagi and Furukawa, 2013; Uematsu and Ushimaru, 2013; Nakahama et al., 2016; Uchida et al., 2016a,b,c; Koyama et al., 2017). Large semi-natural grassland areas (e.g., Aso and Mt. Fuji areas) are considered as regional or local hotspots, which harbor numerous endangered species (Fig. 1 in Kadota et al., 2014; Kitahara and Sei, 2001; Kubo et al., 2009; Ministry of the Environment of Japan, 2014; Uchida et al., 2016a). Narrow meadows around cultivated fields have maintained a high endangered species diversity as well (Kusumoto and Inagaki, 2016; Uchida et al., 2016c). Traditional extensive land-management practices have played as kinds of disturbance to maintain diverse endangered and common grassland plant and animal species, but recently the biodiversity has rapidly decreased due to various land-use changes (see detail in Threat). Thus, the Japanese grasslands and shrublands are local or regional hotspots of endemic or endangered species.

Threats

The flora of subalpine and island grasslands and shrublands is mostly protected within national parks. Although these vegetation have been protected from anthropogenic activities in general, the future climate changes may degrade the vegetation (Hotta et al., 2014; Ministry of the Environment of Japan, 2012). In Mt. Apoi-Dake, grassland area have declined owing to a rapid expansion of Japanese stone pine (*Pinus pumila*) to higher altitude (Ministry of the Environment of Japan, 2012). Reduced snowfall is also the potential driver of the degradation of subalpine grassland and shrubland vegetation by facilitating browsing impacts of sika deer (Takatsuki, 2009). In Bonin islands, feral goats have caused drastic vegetation changes and loss of endemic grassland and shrubland species (Shimizu, 1991).

Riparian grasslands and shrublands have undergone rapid changes to willow-dominated forests in recent decades (Nakamura et al., 2016). Large dams and consolidated river banks, which have been constructed to guard against large disasters by flooding after typhoon events, heavily reduce river disturbance events. This, in turn, has promoted successions from grasslands and shrublands to forest vegetation in riparian zones (Washitani, 2001; Nakamura et al., 2016). In addition, coastal vegetation maintain many endangered species that rapidly declined during recent decades (Sawada et al., 2006). The major driver of the declines is coastal

development. Currently, 41% of Japan's coastal lines have been "developed" with concrete to counteract tsunamis or big waves associated with typhoon-induced surges.

As for semi-natural grasslands, the areas have decreased during the last century, mainly due to land-use changes in Japan. After World War II, drastic population migration from rural to urban (industrial) areas has occurred within the country under very rapid economic growth, in which industrial structure shifted from agriculture to manufacturing during the late 1950s to the early 1970s. The situation caused various land-use changes in semi-natural grasslands, which in turn resulted in rapid loss and degradation of semi-natural grasslands in Japan (Ministry of the Environment of Japan, 2016). Over the past 80 years (c. 1920–2000), semi-natural grassland areas have largely declined throughout Japan: approximately 38,000 km² of semi-natural grasslands existed at the beginning of the 20th century (c. 10.1% of Japan's total lands), but only c. 4300 km² grassland (c. 1.1% of total land area) remained in 2000 (Ogura, 2006). Based on our own estimation using the 5th vegetation survey data, the total area of semi-natural grasslands including ski and training ground grasslands is c. 5600 km² (c. 1.5% of the total land surface) (Fig. 2). Although the estimates were different, there is agreement that only a small fraction of the grasslands has remained today. Additionally, *satokusachi* meadows have rapidly declined after World War II: total *satokusachi* meadow area was of 3090 km² in 1956, but they decreased to 1850 km² in 2010 (Ministry of Agriculture, Forestry and Fisheries of Japan, 2016).

Major drivers of semi-natural grassland loss have been abandonment, intensified use, afforestation and urban development in Japan as in other Palaearctic areas (Török and Dengler, 2018). After World War II, the energy and green revolutions in rural areas have promoted abandonment of husbandry and green manure production, and subsequently the conversion of grasslands into other land uses (Ministry of the Environment of Japan, 2012). Depopulation and aging farmers in rural areas further have accelerated this trend (Normile, 2016; Osawa et al., 2016b).

Land abandonment that promotes subsequent vegetation succession to forests is the most influential driver of declines in grassland specialist species in Japan (Suka et al., 2012; Nagata and Ushimaru, 2016; Uchida et al., 2016a). Huge semi-natural grassland areas are considered to have changed to secondary forests, although there were no reliable data on how much grasslands have been abandoned to date (Ministry of Environment of Japan, 2016). Paddy field abandonment has caused not only endangered species declines but also decreases in almost of all grassland species diversity in Japan (Fukamachi et al., 2005; Uematsu et al., 2010; Uchida and Ushimaru, 2014; Osawa et al., 2016b; Uchida et al., 2016c).

Management method changes in remaining semi-natural grasslands have often occurred during recent decades due to labor-saving and/or loss of local traditional knowledge, causing grassland biodiversity loss (Suka et al., 2012). For example, in Kiso area, a central part of Honshu, abandonment of the traditional practice has caused plant and butterfly species declines (Nagata and Ushimaru, 2016; Uchida et al., 2016a). Recent changes in mowing timing were responsible for declines in reproductive success and genetic diversity of an endangered grassland plant species, *Vincetoxicum pycnostelma* in meadows (Nakahama et al., 2016). The knowledge of traditional practices is diminishing year by year via new socioeconomic drivers such as the introduction of large machinery agriculture and aging farmers (Uchida and Ushimaru, 2014; Uchida et al., 2018a). Because traditional practices are very diverse depending on grassland type and region, we need to find ways to pass down these practices to the next generations.

The effects of intensified use (i.e., land consolidation and nitrogen input) are conspicuous in *satokusachi* meadows around paddy fields in Japan. Paddy consolidation, which converts narrow, irregular and poorly drained paddy fields into wide, quadrangular and well-drained fields to improve productivity and to allow mechanized farming, rarely leads to grasslands that resemble the original ones in composition and structure (Matsumura and Takeda, 2010; Uematsu et al., 2010). More than 65% of paddy fields are now consolidated (Ministry of Agriculture, Forestry and Fisheries of Japan, 2019), which largely reduced plant and herbivorous insect diversity via changing management frequency and characteristics of the surrounding landscape (Uchida and Ushimaru, 2014). The effects of nitrogen input on biodiversity of pastures have not been conspicuous in Japan, although the negative effects are well known to cause biodiversity loss in European semi-natural grasslands (Kleijn et al., 2009; Dengler and Tischew, 2018; Török et al., 2018). Pastures and meadows are usually established on *kurobokudo*, which typically consists of volcanic ash and humus and is very acidic (pH < 5.7) and oligotrophic (<200 mg P₂O₅/kg) (Hiradate et al., 2008; Nagata and Ushimaru, 2016; Koyama et al., 2017). Manuring had always failed to effectively improve productivity of Japanese pastures due to the oligotrophic soil conditions and had been gradually discouraged (Numata, 1961). Nutrient input and neutralization of the formerly acidic soil in consolidated paddy fields can cause declines in rare plant species (Uematsu and Ushimaru, 2013) and increases of invasive alien plants, such as *Andropogon virginicus*, *Erigeron annuus* and *Solidago altissima* (Hiradate et al., 2008). For areas promoting intensified livestock farming, farmers improved pastures via replacing native grass and herb species by introducing alien ones (Numata, 1961). For example, large semi-natural grassland areas in Aso were converted to sown pastures by the national grassland improvement project. Similarly, huge semi-natural grassland areas of eastern Hokkaido were "improved" into sown pastures, dominated by non-native grass *Poa pratensis* from Europe, until the 1960s (Numata, 1961).

Moreover, conversion of pastures and meadows to conifer plantations have been promoted for post-World War II rebuilding since the 1950s. The total area of plantations drastically increased from c. 49,700 km² in 1952 to c. 102,900 km² in 2012 according to various data from the Ministry of Agriculture, Forestry and Fisheries. However, there are no reliable statistics on how much semi-natural grasslands have been converted to plantation in Japan.

Rapid urbanization since the 1960s has also caused drastic decreases in lowland paddy and vegetable fields and riparian floodplain grasslands (Washitani, 2001; Tsuji et al., 2011). Current assessments of the effects of urbanization on biodiversity of *satokusachi* meadows indicate significant negative impacts on grassland plants and animals via habitat loss and degradation (Tsuji et al., 2011; Uchida et al., 2018b).

Overall, areas of natural and semi-natural grasslands and shrublands are rapidly lost owing to diverse human impacts. As a consequence of the widespread loss and fragmentation of natural and semi-natural grasslands and shrublands, plant and herbivorous insect diversity has declined drastically (Suka et al., 2012; Koyanagi and Furukawa, 2013).

Conservation, Restoration and Sustainable Management

As above stated, grassland and shrubland biodiversity has been rapidly threatened by various drivers in Japan. On that account, a variety of biodiversity conservation and restoration activities have been conducted to meet differentiated necessities. Currently, subalpine (subarctic) and island grasslands and shrublands and those on specific soils are mainly protected in national parks, so the national (Ministry of the Environment of Japan and the Forestry Agency and the Cultural Agency of Japan) and local governments direct the conservation planning, to which researchers and local organizations contribute as well. Similarly, the national (Ministry of Land, Infrastructure, Transport and Tourism of Japan and Ministry of the Environment of Japan) and/or local governments manage conservation and restoration of grasslands and shrublands in riparian and coastal areas, with consultation of academic societies and local organizations. Meanwhile, many different stakeholders, including governments, citizens, local committees, non-profit organizations (NPOs) and scientists (for details, see below) have conducted conservation and restoration of semi-natural grasslands, which are predominantly private lands or local commons.

Legal Conservation and Restoration Status

The principal parts of the natural and several expanses of the semi-natural grasslands and shrublands are conserved as parts of the national and quasi-national parks in Japan. Feeding damage on rare plant species by sika deer, however, has become serious in some subalpine areas (natural grasslands and shrublands of the South Japan Alps and the semi-natural grasslands in Kirigamine). In such areas, deer fences have been constructed to protect the vegetation. In Bonin islands, a World Heritage site, eradication of feral goats has been conducted by the Tokyo Metropolitan government to restore natural grasslands and shrublands. In several islands, all the goats were successfully eradicated and natural grasslands and shrublands have been restored (Hata et al., 2010), although long-lasting negative effects of goat grazing and trampling on soil conditions have limited full restoration of natural grasslands and shrublands (Osawa et al., 2016a; Hata et al., 2019, Fig. 4H). In addition, a small area of semi-natural grassland, which has been maintained in the Kaida Plateau, Nagano prefecture, is conserved as a reserve for some endangered species of plants and insects by the local prefectural government (Nagata and Ushimaru, 2016; Uchida et al., 2016c). As special cases, several endangered semi-natural grassland plants and insects (e.g., *Polemonium kiushianum*, *Agapanthia japonica* and *Celes akitanus*) as well as island grassland and shrubland species (e.g., *Patrinia triloba* var. *kozushimensis*, *Symplocos kawakamii* and *Parnara ogasawarensis*) are protected under the Law for the Conservation of Endangered Species of Wild Fauna and Flora and similar local regulations.

Although global warming is believed to significantly influence grasslands and shrublands, especially those in subalpine (subarctic) zones and islands, the expected impacts have been poorly investigated (Ministry of the Environment of Japan, 2012). The national government has promoted the enhancement of scientific knowledge on global warming impacts and how to adapt to them under Climate Change Adaptation Act which were enacted in 2018.

Semi-natural Grassland Conservation

To conserve semi-natural grasslands, support measures as well as regulatory measures should play an important role under the current socioeconomic situations. Regarding an international approach, GIAHS designation by FAO encourages semi-natural grassland conservation activities of local communities in the Aso area and in the tea plantation areas of Shizuoka. In the light of national and local approaches, ASO Grassland Restoration Committee (AGRC) has been established under the Act on the Promotion of Nature Restoration. The AGRC is facilitating local activities for conservation and restoration of semi-natural grasslands by engaging in promotions of sustainable use of the grasslands, biodiversity conservation, environmental education, ecotourism and adding of values to grassland resources by supporting scientific researches (AGRC, 2017). Some subsidy schemes for conservation of semi-natural ecosystems to farmers by national and local governments exist but are operating insufficiently for grassland conservation.

During the last decades, people have realized the values of semi-natural grasslands in the terms of low-cost resources for modern husbandry and biodiversity and cultural landscape conservation (Japanese Society of Grassland Science, 2010). These social backgrounds have promoted a variety of public and private activities for conservation and restoration of Japanese semi-natural grasslands (Japanese Society of Grassland Science, 2010; Ushimaru et al., 2018). Abandoned or unmanaged semi-natural grasslands have usually been restored by reintroduction of burning, grazing and/or mowing: Reintroduction of traditional management schemes combining spring burning and autumn mowing successfully restored plant richness in Aso (Koyama et al., 2017). Although burning is an unfamiliar restoration measure in European counties (Valkó et al., 2014), it is very effective together with use of mowing for meadow biodiversity maintenance in Japan (Nagata and Ushimaru, 2016; Koyama et al., 2017) like in North America (Valkó et al., 2014). Reintroduced extensive cattle grazing has resulted in an increase in autumn-blooming species and in population size of an endangered *Pulsatilla cernua* in an abandoned pasture (Japanese Society of Grassland Science, 2010). To restore meadow biodiversity, reintroduction of mowing is effective as well. Removal of the tall grasses, *Miscanthus sinensis* and *Pleioblastus chino* var. *viridis* from abandoned meadows by reintroduced mowing effectively increased species richness or a population of

endangered species (Japanese Society of Grassland Science, 2010; Hashimoto et al., 2012). Reintroduction of mowing should also be suitable to restore narrow meadows around abandoned paddy fields (Ushimaru et al., 2018). Yet, only a handful of restoration projects have examined the effects of management reintroduction on restoration of abandoned or degraded pastures and meadows in Japan. Therefore, no clear recommendations can be made currently. For example, in Koshimizu Nature Reserve, Hokkaido an experimentally introduced combination of burning and grazing management unexpectedly increased the alien plant dominance, suggesting the importance of continuous monitoring and adaptive management strategy (Tsuda et al., 2002). Thus, accumulating knowledge of semi-natural grassland management through studying grassland restorations is needed to establish the modern ways of grassland managements.

Acknowledgments

We thank Jürgen Dengler and Péter Török for inviting us to write the chapter and giving us constructive advice. This work was supported by grants-in-aid for A. Ushimaru from The Japan Science Society for the Promotion of Science (Nos. 20770015, 23570024, 17K07557, 16H02993 and 19H03303) and Ichimura foundation for New Technology (26-10, 27-9, 28-12).

Glossary

Deccan Plateau Deccan Plateau is the large, inverted triangle-shaped plateau that comprises the Indian Peninsular.

Ecoregions Ecoregions are relatively large units of land or water containing a distinct assemblage of natural communities sharing a large majority of species, dynamics, and environmental conditions (definition from [Olson et al., 2001](#)).

Relict species Relict species is a taxon that was once widespread and diverse, but where the current occurrence has been reduced to a relatively more restricted area, usually through geological time and events.

Succession Succession is an ecological process of change of an ecological community or vegetation composition. The process will include several seral or intermediate communities until it reaches a stable state, or climax community, determined by the interactive environmental variables in the area. The process can include several associated states as defined below:

- Climax stage is the stable ecological community achieved at the end of the succession process, and will remain relatively unchanged in the absence of disturbances.
- Deflected succession is a process where a vegetation community is maintained in a quasi-stable by continuous or frequent human activity that prevents the system from achieving a climax state.
- Disclimax is a vegetation community which is maintained in a stable but subclimax state due to constant or frequent disturbances.
- Edaphic climax is a vegetation community that is maintained primarily by substrate conditions, such as soil type, moisture, depth, topography, etc.

Abstract

Grasslands have an ancient history in South Asia. Reconstructions of geological history and biogeography indicate that grasslands spread through South Asia after the northward drifting Deccan Plate collided with the northern Laurasian continent about 40 million years ago. The larger, distinctive patches of grasslands in South Asia are the Terai-Duar alluvial grasslands and savanna along the floodplains of the Ganges River system, the large shola grasslands on the high elevation hill slopes and plateaus of the Western Ghats mountains, the *Banni* and *Vidi* grasslands of Gujarat in northwestern India, the plateau and valley grasslands along the Satpura and Maikal mountain ranges in north-central India, the dry grasslands of Andhra Pradesh and Tamil Nadu plains in the south and central regions of the Indian peninsula, and the montane patana grasslands on the southeastern slopes of the central mountains of Sri Lanka. Most South Asian grasslands are disclimax or edaphic climax communities. Some scientists consider these to be interim 'stable' states, maintained through 'deflected succession' due to continuous disturbances that keep setting back successional processes, preventing the ecosystems from attaining a 'climax stage.' Some grasslands, are, however, maintained by edaphic conditions, where the soil conditions prevent growth of trees, and the grasslands are considered to be an 'edaphic climax' community. These South Asian grasslands now harbor a rich biota, with many faunal species having adapted their behavior to the ecological dynamics of grasslands. For example, several birds time their nesting and mating periods to coincide with grassland dynamics drive by seasonal floods and fires. The South Asian grasslands are also especially important for grazing herbivores that include large deer, Asian elephant, and Greater One-horned Rhinoceros. Where ungulate prey gather predators follow; thus, the grasslands support high densities of Asia's largest predator, the Tiger.

What Are Grasslands? Back to Basics

A grassland is easy enough to identify by sight as an area dominated by grasses. But it's a challenge to define ecologically because the ecosystem processes that determine its physiognomy are complex. As a result, there are several definitions of grasslands that focus on structure, function, and even on the absence of specific features, such as woody plants and trees (Gibson, 2009). But there are three characteristics that unite most of these definitions (Gibson, 2009). The first is the dominance of grasses, or members of the plant Family Poaceae. Second, is the low abundance of wood vegetation; usually trees. Third is a generally arid climate. Other characteristics that are included in the range of definitions include deep and fertile soils, frequent disturbances from fires and floods or grazing, and soil types. This general inability among scientists to define what seems to be a fairly simple ecosystem actually hides the highly dynamic and responsive nature of grasslands that are maintained by various drivers of environmental change or conditions that attain different levels of importance based on where the grasslands are. White et al. (2000) simplified this conundrum by providing a working definition of grasslands as "terrestrial ecosystems dominated by herbaceous and shrub vegetation and maintained by fire, grazing, drought and/or freezing temperatures." This straightforward-sounding definition then includes the physiognomy and the drivers that maintain the grasslands.

Grasslands occur in every continent on Earth, except for Antarctica (White et al., 2000). They cover an estimated 40% of the Earth's land area, although this is based on a broad inclusion that of savannas, shrublands, and tundra (Gibson, 2009; White et al., 2000). Grasslands support rich ecological communities—visualize the Serengeti Plains of East Africa with teeming herds of wildlife. They are critically important habitats for breeding, migrating, and wintering birds, support rich and diverse soil faunas, and are feeding grounds for diverse ecological communities of wild ungulates that in turn support some of the most charismatic mega-predators on Earth.

Grasslands also provide a multitude of ecosystem goods and services to support human communities and have done so for millennia. Over the centuries they have been extensively cleared for agriculture, but they are also the storehouses for source pools of grains such as wheat, corn, rice, rye, millet, and sorghum that have supported civilizations. Even now, grasslands are the primary source of genetic resources for improving agricultural crops. They have been pastures for livestock tended by ancient and present pastoral communities. Grasslands are important to cycle water and nutrients, and they help to store below-ground carbon, contributing to limit global warming.

Unfortunately, grasslands the world-over are highly threatened by various drivers of change, especially from conversion to agriculture, urbanization and human settlement, desertification, exotic invasive species, and fragmentation (Gibson, 2009; White et al., 2000).

Biogeographic Origins of South Asia and South Asian Grasslands

South Asia, consisting primarily of the Indian Subcontinent, is the geographical reference to the landmass to the south of the Himalayan Mountain range, and bordered on the east and west by the Ganges and Indus River valleys, respectively. The region is represented by seven countries, namely Bangladesh, Bhutan, India, Maldives, Nepal, Pakistan, and Sri Lanka. In addition to these political entities, there are 55 terrestrial ecoregions represented in this region, including those that extend into the high Himalayas (Fig. 1). With the exclusion of the alpine meadows along high elevations of the Himalayan range, the only extent of grasslands that are large enough to qualify as an ecoregion in spatial scale (see Olson et al., 2001 for treatise on ecoregions), is the Terai-Duar Grasslands and Savannas ecoregion, which extends as a long, narrow swathe from northwestern India, through the southern regions of Nepal and Bhutan and eastern India (Fig. 1, Wikramanayake et al., 2002). Most of the other terrestrial ecoregions in South Asia belong to dry deciduous forests, thorn scrub forests, or tropical and subtropical broadleaf forests.

Despite the relatively less predominance and representation in South Asian ecoregions, grasslands have relatively ancient histories in South Asia, and date back several million years, as reconstructed by multiple sources of circumstantial evidence. The biogeographic origins of the present-day South Asia region are traced back to the southern supercontinent known as Gondwanaland, which comprised of an amalgamation of the African, Antarctic, Indo-Australian, and South American tectonic plates during the late Jurassic period. When this continent broke up during the Cretaceous period, about 100 million years ago, the tectonic plate bearing the area that now forms much of the Indian Subcontinent, began a slow drift northward, until it collided with the northern Laurasian continent that is now Central Asia. The collision, about 40 million years ago (Bouilhol et al., 2013), created violent geological uplifts that formed the Himalayas, that contain the highest mountain peaks on Earth. The Indian subcontinent, or the plate which contains most of the Deccan Plateau and Sri Lanka, thus harbors relict species of the ancient southern flora and fauna with links to Africa and Madagascar (Srivastava, 2011; Prasad et al., 2013).

The grasslands of South Asia likely spread through the subcontinent long after the collision, following the long continental voyage. The evolutionary history of grasslands throughout the world can be broken down into distinct stages in paleobiogeographic history, covering a period known as the Paleogene, which began 66 million years ago and lasted for about 43 million years, and the subsequent Neogene period that lasted until about 2.5 million years ago (Strömberg, 2011). During the Paleogene, the Earth's climate shifted from warm and humid conditions to a cooler and drier environment. This was the period when the Indian Subcontinent was closer to its current position, and in the process of colliding with the northern continent of Laurasia. This was also the period when mammals began their great diversification, during the latter part of the Paleogene, an era known as the Oligocene,

Fig. 1 The locations of the major grassland ecosystems of South Asia, in relation to the ecoregions of South Asia. More details about the ecoregions can be found in Wikramanayake et al., 2002, and at <http://ecoregions2017.appspot.com/>. The grasslands occur as scattered vegetation types or ecosystems within the ecoregions that represent regional-scale ecosystems. The only distinctive grassland ecosystem to be recognized as an ecoregion is the Terai-Duars along the base of the Himalayan mountains, where annual flooding of the Ganges and Brahmaputra rivers scours the alluvial floodplains, creating conditions that encourage and maintain grasslands.

about 32 million years ago. This diversification of mammals and the fossil teeth they left behind provides one line of evidence to trace the history of grasslands, another being pollen counts (Strömberg, 2011 and references therein).

As the climate continued to cool there was a shift in vegetation. Many of the larger tropical plants began to die off and became replaced by grasses and herbs. Thus, the Paleogene period saw the emergence of grasslands. The initial grassland communities included both C_3 and C_4 grasses, adapted to open habitats, but with continued atmospheric cooling, the environment favored C_3 grasses, which began to dominate the grasslands, until the late Neogene, when warming trends turned the tide back in favor of C_4 grasses that spread southwards into the tropical-subtropical latitudes. The C_4 photosynthetic pathway allows grasses to fix carbon more efficiently under high temperatures, aridity, and low atmospheric CO_2 conditions than the C_3 pathway, and favor their growth in tropical and subtropical lowlands and areas with warm-season precipitation (Ehleringer and Cerling, 2002).

Grasslands of South Asia. Where They Are

Although not large enough to be considered ecoregions on their own, there are several areas with relatively extensive grasslands in South Asia (Fig. 1). All are considered to be disclimax or edaphic climax communities. The most extensive is, of course the alluvial grasslands and savanna along the base of the Himalayan mountain range, which has been recognized as an ecoregion (Wikramanayake et al., 2002). These grasslands—considered to be the tallest in the world because of the wild sugar cane (*Saccharum spontaneum*) grasses that can grow to over seven meters tall and effectively tower over elephants that wander through them—grow in the floodplains of one of Asia's largest and most revered river systems, formed by the Ganges and Brahmaputra Rivers.

Other less extensive, but nevertheless significantly large areas of grasslands occur in the Indian Subcontinent; estimates derived from satellite imagery indicate that about 17% of the land area of India is covered by grasslands (White et al., 2000), but these include the alpine meadows of the high Himalaya, the alluvial grasslands along the base of this mountain range, and the scattered grasslands further south in the Deccan Plateau. The more extensive of the latter grasslands are found on the high elevation rocky hill slopes and plateaus of the Western Ghats mountain range that runs parallel to the western coast of the Indian peninsula, or Deccan

Plateau, the 'Banni' and 'Vidi' grasslands of Gujarat, the plateau and valley grasslands along the Satpura and Maikal mountain ranges in the north-central regions of the Indian peninsula, and the dry grasslands of Andhra Pradesh and Tamil Nadu plain in the south and central regions of the Indian peninsula (Rawat and Adhikari, 2015). Further south, the island of Sri Lanka has several grasslands on the southeastern slopes of the central mountains (Pemadasa and Mueller-Dombois, 1979; Mueller-Dombois, 1968).

Ecological Dynamics of South Asian Grasslands. How Are They Maintained?

What maintains the grasslands of South Asia is an important question to explore because there are many different points of view proposed on whether these grasslands are 'climax' ecosystems, or an interim stage in the 'successional process.' A climax community represents the 'stable' 'end point' along the process of recovery of an ecosystem that has been disturbed. Some scientists consider the South Asian grasslands as being an interim 'stable' state and maintained through a process termed 'deflected succession,' where the grasslands maintained by relatively continuous or frequent disturbances or forces that keep setting back the successional processes, thus preventing the ecosystems from attaining the 'climax stage.' The disturbances that set back succession can be floods, fire, frost, or even diseases that can kill trees and cause widespread changes to the ecosystem composition. Or they can even be anthropogenic forces such as unsustainable harvesting of trees for a variety of purposes, from construction to firewood, as well as grazing livestock or fires set to create pastures or hunting grounds. Some grasslands, are, however, maintained by edaphic conditions, where the soil depth or composition prevent growth of trees, and the grasslands are considered to be an 'edaphic climax' community. However, with time, as the top soils begin to develop through weathering, these grasslands can succeed into forests or savannas.

For example, research and analyses of human settlement patterns in the Western Ghats point to frequent fire set by early pastoral and agricultural communities as the primary driver that maintains the grasslands, known as *Shola*, in the hills of this mountain range (Thomas and Palmer, 2007). More recent analyses have also shown that topography and bioclimatic variables such as ambient and soil temperature regimes, moisture and precipitation determines the configuration of the grasslands and forests in the matrix, with slopes that are more affected by insolation and lack of moisture and greater proneness to fires being clothed with grasslands, while forests grew in shaded valleys (Das et al., 2015). Thus, ecological dynamics of grasslands are complex and complicated.

In Sri Lanka, the origin and maintenance of the montane *Patana* grasslands are also under contention, with some researchers pointing to a 'disclimax' state, or a 'stable state' maintained below a climax state, due to frequent burning (Holmes, 1951), while others argue for an ecosystem maintained by edaphic conditions (De Rosayro, 1946); however, this conflict has not been resolved (Pemadasa, 1990).

Biodiversity of South Asian Grasslands

The grasslands of South Asia harbor a rich biota, with many faunal species having adapted their behavior to the ecological dynamics of grasslands through the millennia. Several birds time their nesting and mating periods to coincide with grassland dynamics. Species such as the Great Indian Bustard (*Ardeotis nigriceps*) and Lesser Florican (*Sypheotides indicus*) are now highly threatened because of loss of grasslands and disruption of the seasonality of the dynamics that maintain grasslands. The South Asian grasslands are also especially important for the grazing herbivores that include large deer such as Sambar (*Rusa unicolor*), Spotted Deer or Chital (*Axis axis*), Blue bull or Nilgai (*Boselaphus tragocamelus*), Blackbuck (*Antelope cervicapra*), as well as Asian elephant (*Elephas maximus*), and Greater One-horned Rhinoceros (*Rhinoceros unicornis*). Where ungulate prey gather in numbers, the predators will follow; thus, the grasslands support some of the highest densities of Asia's biggest and most charismatic predator, the Bengal Tiger (*Panthera tigris*). Other predators such as Striped Hyena (*Hyaena hyaena*) and Indian Wolf (*Canis lupus pallipes*) also use these grasslands and the high prey densities they offer. Over the ages, species like Blackbuck (Fig. 2) and Swamp deer (*Rucervus duvaucelii*) (Fig. 3) have evolved and adapted to specific grassland types. Larger carrion seeking birds such as vultures also gather in the grasslands. The Indian grasslands have a rich assemblage of vultures that include Red-headed vulture (*Sarcogyps calvus*), White-backed vulture (*Cyps africanus*), Long-billed Vulture (*Cyps indicus*), Slender-billed Vulture (*Cyps tenuirostris*), and Egyptian Vulture (*Neophron percnopterus*). The isolated patches of montane grasslands have also been recognized as centers of endemism, and adaptation (Das et al., 2015; Rodgers and Panwar, 1988).

Terai Duar Grasslands and Savanna of India, Nepal and Bhutan

These grasslands cover the floodplains of the rivers that cascade down from the Himalayan Mountains into the lowlands and inner valleys and bring down large silt loads that are deposited in the floodplains. Large silt loads are also carried far by the two major rivers, the Ganges flowing from the west and Brahmaputra from the east and become confluent, to the Bay of Bengal where they sustain the largest mangrove in the world, the Sunderbans.

These grasslands extend as a narrow swathe from northwestern India's Himachal Pradesh, through southern Nepal into Bhutan and Arunachal Pradesh further east in India (Fig. 1). The ecoregion name is derived from the colloquial name for these grasslands, known as the *Terai* in the western range and *Duars* in the east.

Fig. 2 Blackbuck, *Antelope cervicapra*, are adapted to live in short grasslands and are now found in isolated populations in northwest India and western Nepal, where they live in a semi-captive state. They are fast runners enabling them to escape predation by the Asiatic Cheetah, *Acinonyx jubatus venaticus*, which is now extinct in India. Courtesy: E. Wikramanayake.

The climate is hot and humid in the summer months, especially immediately before the torrential monsoon rains begin, when temperatures can exceed 40 °C. But the winters are cool, dropping low enough to form morning ground frost. A blanket of fog and low clouds in the winter overlies the grasslands and can remain until late morning, adding to the winter chill. It is this extreme

Fig. 3 Swamp deer or *barasingha*, *Rucervus duvaucelii*, are adapted to live in marshy alluvial grasslands of the Terai Duar Savanna and Grasslands ecoregion. This species is now mostly confined to a few protected areas along the base of the Himalayan Mountain range in southern Nepal and Northern India. Courtesy: E. Wikramanayake.

Fig. 4 The monsoon clouds darken the skies over the Terai grasslands in southern Nepal. The mature flower stalks of wild sugar cane, *Saccharum spontaneum*, will shed seeds that will regenerate the grasslands after the floods scour the alluvial plains, resetting succession. Courtesy: E. Wikramanayake.

monsoonal seasonality that maintains the *Terai-Duar* grasslands (Fig. 4). The combination of annual floods from the gushing, silt-laden mountain rivers and to a lesser extent, fires set back succession by flushing and burning the floodplains and clearing the saplings and seedlings from the encroaching forest trees, but the grasses regenerate rapidly after the floods and fires. But scattered trees *Bombax ceiba* or silk cotton trees, or smaller patches of evergreen and deciduous broadleaf forests can survive, adding some savanna-like definition to the landscape vegetation.

The grassland communities are also quite variable, with the species compositions determined by the fluvial and fire-related disturbances, edaphic conditions, moisture, and the hydrological and hydraulic processes from floods. For instance, as the rivers change course from alluvial deposition and water flow intensities, they can leave behind isolated ox-bow lakes, abandoned channels, and new alluvial depositions, all of which can support different grassland communities in this highly dynamic landscape.

The alluvium replenishes the floodplains and enhances the productivity of the grasslands, which provide nutrition to a rich assemblage of small to large herbivores. The latter that includes some of Asia's largest terrestrial animals, such as Asian elephants, Greater One-horned Rhinoceros, Wild Water Buffalo (*Bubalus arnee*), Guar (*Bos gaurus*), Sambar, and Swamp Deer. The high densities of these ungulates also support high densities of predators, including Asia's largest, the charismatic Bengal Tiger. Great Hornbills (*Buceros bicornis*), Sarus Crane (*Grus antigone*), Bengal Florican (*Houbaropsis bengalensis*), several species of vultures, and Lesser Adjutant Stork (*Leptoptilos javanicus*) add to the charismatic avian community, while the rivers support mugger crocodiles (*Crocodylus palustris*), gharial (*Gavialis gangeticus*), Gangetic river dolphins (*Platanista gangetica*) and large mahseer fish (*Tor* spp.).

Grazing is another ecological process that contributes to the grassland structure and composition. Historically, most grazing was by the diverse community of ungulates, from small Muntjak or barking deer (*Muntiacus muntjac*) and Hog deer (*Axis porcinus*) to the larger sambar, swamp deer, water buffalo, rhinoceros and elephants. But now herds of domestic cattle also contribute to grazing intensity and influence the vegetation community diversity and distribution, and contribute to the degradation of grasslands, setting back the disclimax state even further.

The early studies of the Terai grasslands conducted by Lehmkühl (1994) and Peet et al. (1999) describe several grassland vegetation assemblages, including different successional stages. In general, the grassland assemblages are influenced by moisture levels and disturbance. The grasslands in permanently wet or seasonally inundated areas are dominated by tall grasses such as *Phragmites karka* and *Saccharum spontaneum*, while drier areas are dominated by *Narenga porphyrocoma* and *Themeda arundinacea*. Abandoned agricultural sites are characterized by the shorter *Imperata cylindrica*. Grazing lawns with short grasses and forbs are interspersed amidst the large patches of tall grasslands (Karki et al., 2000), and are dominated by *Imperata cylindrica*, *Saccharum spontaneum*, *Vetiveria zizanioides*, and *Desmostachya bipinnata*, but kept cropped down by the community of grazing mammals, including included Chital, Swamp deer, Hog deer, Greater one-horned rhinoceros, and Muntjak.

Peet et al. (1999) went further, and described nine grassland vegetation communities from the Terai, based on sampling in protected areas in Nepal, which now support the remaining refuge remnants of these grasslands. Community composition was described on the basis of the dominant species, which were generally represented by five or less species that contributed to the total vegetative cover. The assemblages are:

1. *Typha elephantina* assemblage that grows in permanently water-logged sites
2. *Phragmites karka*-*Saccharum spontaneum* assemblage that grows in seasonally inundated and heavily grazed areas
3. *Phragmites karka*—*Saccharum spontaneum*—*Saccharum arundinaceum* assemblage
4. *Phragmites karka* assemblage, a tall, dense riverine grassland community that grows in seasonal and permanent marshes
5. *Saccharum spontaneum* assemblage, which is a phase that can include a mixed *Saccharum spontaneum*—*Dalbergia sissoo* association in the floodplain grasslands and alluvial soils that are often inundated
6. *Imperata cylindrica* assemblage that grows in dry areas with well-developed soils and usually have been previously cultivated.
7. *Imperata cylindrica*—*Narenga porphyrocoma* assemblage, where the *Imperata cylindrica* dominated assemblage is invaded by the taller grasses
8. *Narenga porphyrocoma* assemblage, which are tall, dense grasslands that grow along old river terraces and wetter sites that are also influenced by fire
9. *Themeda arundinacea* assemblage, which is a tall, dense grassland usually found along the forest edge and on well-developed soils and influenced by fire.

The Banni and Vidis Grasslands of Gujarat, India

The Banni and Vidis grasslands are located along the northern border of Kachchh district and in the Saurashtra peninsular region of Gujarat, respectively, and form some of the largest areas of contiguous grasslands in India (Kumar et al., 2015, Mehta, 2015, Figs. 5 and 6). The term 'Banni' is derived from the local Kachchhi dialect for 'Bannai,' which means 'freshly made' in reference to the land that has been formed by detritus and sediments brought down by the Indus, Luni, Banas and Saraswati rivers which flowed through this region in the recent geological past (Kadikar, 1994 – in Kumar et al., 2015).

The Banni grasslands consist of a matrix of wetlands and grasslands and are considered to be mid-successional or subclimax grasslands (Roy and Singh, 2013). Over 37 species of grass belonging to the genera *Sporobolus*, *Dichanthium*, *Lasiurus*, *Cenchrus* and *Eragrostis* have been recorded in these grasslands.

The Banni grasslands were once managed under a traditional rotational livestock grazing system, which has now broken down, causing the grasslands to degrade under intense and continued grazing by domestic livestock. Consequently, the grasslands are being invaded by *Prosopis juliflora*, a robust, highly invasive colonizing tree species. Water scarcity is also driving the grasslands to desertification.

The Vidis grasslands in Saurashtra, in the western peninsular region of Gujarat state grow under semi-arid and hot conditions. The vegetation is described as scrub savanna, with a high proportion of graminoids (Mehta, 2015). Despite the low productivity and sparse vegetation cover, the Vidis have been traditionally used by local pastoral communities for livestock grazing. The grasslands used to be continuous, with a relatively rich grass cover, but with the expansion of agriculture, human settlements, industries, and subsequent invasion by *Prosopis julifera*, by the second half of the 20th century the grassland landscape has been heavily fragmented.

Fig. 5 Banni grasslands of the dry and arid regions of northwestern India include wetlands that support species associated with wetlands, such as the common crane (*Grus grus*). Courtesy: Manoj Dholakia.

Fig. 6 *Vidis* grasslands in the western peninsular region of Gujarat are home to the Asiatic lion (*Panthera leo*). Smaller species such as the Four-horned antelope or *chinkara* (*Gazella bennetti*) can survive these semi-arid, hot conditions without drinking water for several days, depending on moisture from plants and morning dew. Courtesy: Shikha Bisht/G.S Rawat.

About 58 species of grasses have been recorded from these grasslands, defining nine recognizable grassland communities, which are determined by different habitats, micro-geomorphic conditions among other factors. For instance, the hilly to mild undulating terrain on gravel soil and basalt are characterized by a *Sehima-Dichanthium* dominated community, while *Sehima-Aristida* characterize the piedmont slopes and foothills. A *Bothriochloa*—*Aristida* dominated community grows on dry hills and hillocks with mild grazing, while the low-lying heavy soils and alluvial plains consists of a *Cenchrus*—*Dichanthium* community, and an *Eragrostis-Aristida* community dominates highly degraded grasslands with sandy soils. Xerophytic thorny trees such as *Acacia* spp., *Zizyphus nummularia*, *Commiphora wightii*, *Maytenus emarginata*, *Balanites aegyptica*, and *Euphorbia* spp. grow scattered throughout.

The *Vidis* grasslands are home to the small, isolated population of Asiatic lion (*Panthera leo*). Other mammals of note in the *Vidis* and *Banni* grasslands include ungulates such as Four-horned antelope or *chinkara* (*Gazella bennetti*), Blue bull, and Blackbuck. The community of predators that are sustained by these ungulates include Indian wolf, Striped hyena, Golden jackal (*Canis aureus*), Jungle cat (*Felis chaus*), Indian fox (*Vulpes bengalensis*), and Common leopard (*Panthera pardus*). The grasslands also support over 250 species of birds including critically endangered grassland specialist birds such as the Great Indian bustard and Lesser Florican.

Shola Grasslands of the Western Ghats, India

The *Shola* grasslands occur as a matrix of montane grasslands and stunted montane forests on the high plateaus and slopes of the 1600 km long Western Ghats mountain range (Fig. 7). The grasslands of Eravikulam National Park, Mukurti Sanctuary, Kodajadri, Bababudangiri, Agastyamalai, and Poochipara in Silent Valley National Park are all examples of *shola* grasslands.

The Western Ghats region is classified as a distinct biogeographic zone of India based on its unique species assemblage (Rodgers and Panwar, 1988). The *shola* grasslands are found atop the highest plateaus, above 1500 m, of the Niligiri, Palini and Anamalai Hills along the mountain range. Phytogeographical analysis has shown that the vegetation, especially of the *shola* forests of the Western Ghats share more similarity to those of the Western Himalayas. This is likely due to the presence of a biogeographic corridor between the Western Ghats and the Western Himalayas along the Vindhya and Satpura mountain ranges of Central India that allowed migration and exchange of species (Gupta, 1990). With the more recent warming trends, the temperate species in the lower mountain ranges would likely have disappeared. Because of these differences, Thomas and Palmer (2007) have suggested that the *sholas* of the Western Ghats and the *patana* grasslands of Sri Lanka should not be clustered as a singular biogeographic unit.

The origins of the *shola* forests and grasslands are also contested. One theory suggests that these grasslands have been in existence long before human occupation in the Western Ghats, and the grasslands evolved due to climatic conditions, with the strong monsoon winds and frost in the winter months stunting the growth of trees in the region (Thomas and Palmer, 2007; Srinivasan et al., 2015). The other theory suggests that the grasslands have originated and remain in a state of permanent flux due to biotic

Fig. 7 Shola grasslands of the Western Ghats Mountains of India. This mosaic of grasslands and forests represent sky islands, where some species that are adapted to the grassland and forest habitats remain isolated in the respective patches. Over time, some species can evolve into endemic species. Courtesy: K. Karunakaran/G.S Rawat.

pressures such as fire, cattle grazing and the extraction of forest products. Humans have inhabited the Western Ghats since the Paleolithic or Old Stone Age, more than 12,000 years ago (Chandran, 1997), and these millennia of human interaction with the landscape have allowed for the evolution of the grasslands in the Western Ghats to remain without turning into the woody vegetation (Pemadasa, 1990; Thomas and Palmer, 2007). Interestingly, experimental research has indicated that burning the land in winter helps curtail the spread of woody plants while also reducing damage to endemics like the *Strobilanthes kunthiana* or *Neelakurinji*, the shrub that blooms once every 12 years to impart a purple-blue hue across the grasslands from which the mountains get their name; Nilgiri, which literally means the blue mountains (Thomas and Palmer, 2007).

The shola grasslands harbor many herbaceous species with a limited geographic distribution (Blasco, 1970). Most grasses are perennial C_4 tussock grass varieties. Characteristic species include *Eulalia phaeothrix*, *Dichanthium polyptychum*, *Themeda tremula*, *Ischaemum indicum*, and species of *Chrysopogon*, *Agrostis*, *Andropogon*, *Arundinella*, *Garnotia*, *Jansnella*, *Eragrostis*, *Poa* and *Helictotrichen* (Chandran, 2015; Srinivasan, 2011).

A flagship species for the shola grasslands is the endemic Nilgiri tahr (*Nilgiritragus hylocrius*), an endangered mountain goat that inhabits the high elevation cliffs and grasslands of the Western Ghats. The presence of this endemic mountain goat in the Nilgiris, should be considered indicative of the importance of developing a deeper understanding of these grasslands (Thomas and Palmer, 2007). Other important species that use the grasslands include the Tiger, Asiatic wild dog or dhole (*Cuon alpinus*), and Gaur (*Bos gaurus*).

The Nilgiri hills in the Western Ghats harbors the best existing example of a shola grassland ecosystem and has been identified as an important center of speciation in southern India, as indicated by the exceptionally high endemism and diversity among floristic and faunal species when compared with the Palni and Anamalai hill plateaus (Blasco, 1970; Srinivasan et al., 2015). In most likelihood many of the species that evolved in the Nilgiris never left this hill top.

Humans have lived in the Western Ghats range for over 12,000 years, with the first recorded evidence of the landscape having been altered due to farming happening around 3000–5000 years ago (Thomas and Palmer, 2007). However, this historic interaction with the landscape was environmentally sustainable and beneficial for the regeneration of the sholas. It was during British colonial rule in India that the landscape of the Western Ghats became vulnerable consequential to human actions, in particular monoculture plantations had a detrimental impact upon the ecosystem. The original swathes of grassland have become converted and fragmented due to agricultural expansion for commercial crops such as tea, Black wattle (*Acaia mearnsii*) and pine (*Pinus patula*) (Srinivasan et al., 2015). The grasslands are also being invaded by exotic species such as Scottish broom (*Cystisus scoparius*), which has destroyed the diversity of the native plant community. Expansion of monoculture plantations of *Acacia mearnsii* and *Eucalyptus globulus* continue unabated. These changes to the landscape have in turn caused changes in the volume and rate of streamflow, and

negatively impacted soil conditions, with increased levels of salinity and acidity (Srinivasan et al., 2015). Such changes to the ecosystem affect the productivity of the landscape for local biodiversity and the people who depend upon it for their livelihoods. Hence, the restoration of the grasslands should be encouraged as it will restore ecosystem services.

Grasslands and Savannas of Sri Lanka

The grasslands of Sri Lanka can be classified into three general groups; the montane grasslands, savannas, and lowland grasslands (Pemadasa, 1984, 1990). The montane grasslands, locally known as *Patana*, cover the slopes of the south-central highlands of the island, above 500 m (Pemadasa, 1990), mainly in the Montane Intermediate Floristic Zone, Horton Plains Floristic Zone, with smaller patches in the Eastern Intermediate Floristic Zone and Knuckles Floristic Zone (Fig. 8). There are different views on the drivers that maintain these *patana* grasslands, with some researchers pointing to historic anthropogenic activities that have removed the forest vegetation (Holmes, 1951), while others attribute it to edaphic conditions that prevent tree growth (De Rosayro, 1946).

A characteristic feature of all *patanas* is their occurrence on mountain slopes (Fig. 9); however, there are also phytosociological and physiognomy dissimilarities as well as other biotic and abiotic differences that makes these grasslands ecologically fascinating and floristically diverse (Pemadasa, 1984). Using complex multivariate analyses, Pemadasa and Mueller-Dombois (1979) were able to distinguish five different types of *patana* grasslands:

1. Humid-zone dry *patanas* that grow predominantly in the western slopes of the island (Kandy, Gampola, Pussellawa and Ramboda), with an annual rainfall of over 2100 mm, with a single dry spell in February. These *patanas* are characterized by the dense bunch-grass species *Cymbopogon nardus* at lower elevations (500–700 m) but transitioning into tussock grasses (*Themeda tremula*) higher up, above 90 m. Other noteworthy species in the humid-zone dry *patanas* include the grasses *Dimeria gracilis*, *Eulalia trispicata*, *Imperata cylindrical* and herbaceous species such as *Desmodium heterocarpum* and *Vernonia* spp. (Pemadasa, 1990).
2. Summer dry zone dry *patana* are confined to the Uva basin, in the south-eastern slopes (Pemadasa, 1984). Climatically, the region is distinguishable for having a long and intense dry spell from June through September, followed by convectional-cyclonic weather that brings over 1500 mm of rainfall between October and November. These *patana* grasslands are characterized for having creeping perennial grasses such as *Alloteropsis cimicina*, *Bracharia distachya*, and *Eragrostiella secunda* (Pemadasa, 1990).
3. Intermediate *patanas* grow on the steep hills between 1500 and 2000 m, in Hakgala, Ohiya and Haputale areas (Pemadasa, 1984), with an average annual rainfall of 2000 mm. These grasslands are characterized by grasses such as *Arundinella villosa*, *Chrysopogon zeylanicus*, *Cymbopogon nardus* and *Themeda tremula* (Pemadasa, 1990).
4. Lower wet *patana* grasslands are found between 2000 and 2330 m in Ambewela, Sita Eliya, Moon Plains and Elk Plains with rainfall similar to the humid zone dry *patana*. These grasslands are heavily grazed by cattle, which creates a stubble-like short turf characterized by *Arundinella villosa* and *Chrysopogon zeylanicus* (Pemadasa, 1984).
5. The Upper wet *patana* are found on the Horton Plains plateau, above 2330 m in elevation, and are distinguished from the lower wet *patanas* as they are cooler and develop overnight ground frost, which is considered an important determinant of vegetation type (Pemadasa, 1984). Some of the dominant species in these grasslands are *Dichanthium polypicum* and *Tripogonbromoides*.

The *patana* ecosystems are now under severe threats from various drivers of environmental change, ranging from mining, agricultural expansion, invasive species, and climate change. Many of the lower wet *patanas* are considered totally extirpated (MoMD&E, 2019). Therefore, urgent interventions are needed to conserve and manage these montane grasslands, especially since several faunal species, especially birds, reptiles, and insects, have evolved their natural histories to adapt to the grassland ecosystems and dynamics. However, for this to happen a better understanding of the ecological dynamics of the grasslands is necessary; many of the previous studies have been descriptive, rather than focused on the ecological processes and dynamics that are critical for management.

Sri Lanka's savannas occur to the north and east of the Uva Basin, between 300 and 500 m, in the Eastern Intermediate Floristic Zone and Hill Savannah Dominant Floristic Zone (Fig. 8). Smaller, scattered patches occur in the Montane Intermediate Floristic Zone, mixed with the *patanas*. These ecosystems are characterized by the presence of fire tolerant tree species, notably *Careya arborea* and *Phyllanthus emblica*. The savannas have been categorized into two types; the upland and lowland savannas, based upon topographic, edaphic, floristic and physiognomic dissimilarities. The upland savannas are comprised of tall grasses that grow up to 1.5 m, dominated by *Cymbopogon polyneuros*, *Themeda tremula* and *T. triandra* Forsk.

The lowland savannas, locally known as *talawa* and *damana* grow in valleys and plains of the eastern and southeastern hillsides around Bibile and Moneragala. These savannas are comprised primarily of *Imperata cylindrica* with scattered trees of *Pterocarpus marsupium* and *Syzygium cumini*.

The savannas are utilized for multiple ecosystem services such as cattle grazing, shifting cultivation, and firewood collection, but are also being converted with urban expansion (MoMD&E, 2019). The spread of the exotic *Megathyrsus maximus*, commonly known as elephant grass, is of considerable concern because it is displacing the native savanna grasses (MoMD&E, 2019).

The lowlands grasslands surround the central highlands and are referred to as pastures by Pemadasa (1984) due to the utilization of these grasslands for grazing. Climatically these grasslands are diverse, and four main lowland pasture types have been described by Pemadasa (1990):

Fig. 8 Distribution of major grassland ecosystems in Sri Lanka. The floristic zones from MoMD&E (2019).

1. Wet pastures that are found extensively within coconut cultivations in the western, south-western and southern lowlands, a region characterized for its perennial rainfall and receiving an annual rainfall of over 2300 mm. These pastures are predominantly comprised of carpet grass species such as *Axonopus compressus* and *Chrysopogon aciculatus* which are popular choices for animal fodder. These grasslands are maintained by intensive management to prevent succession.

Fig. 9 The rolling *patana* grasslands of the montane regions of Sri Lanka are believed to be maintained by fire. The grasslands that grow on steeper slopes are likely in an edaphic climax state, where the thin topsoil cannot support woody plants. Over millennia, several birds, reptiles and insects have adapted their life histories to this cycle of fire and other disturbances. Loss of these grasslands could also affect the survival of these faunal species. Courtesy: Kithsiri Gunawardena.

- Intermediate pastures are maintained by forest clearing for coconut plantations in the north-western lowlands, where rainfall is around 2000 mm. The pastures are used for cattle grazing. Floristically the pastures are comprised of both wet and dry pastures species such as *Aristida setacea*, *Axonopus compressus*, *Chrysopogon aciculatus* and *Cyrtococcum trigonum*.
- Dry pastures in the northern, north-central and north-eastern lowlands of Sri Lanka are largely disclimax ecosystems that have been maintained as grasslands by frequent anthropogenic disturbances since the abandonment of cultivated land during ancient times. These areas receive about 1400 mm of annual rainfall during the North-eastern monsoon period. Floristically, species variation occurs depending upon edaphic conditions. *Imperata cylindrica* dominates alluvial areas, while the dense-tufted *Aristida setacea* grows in areas with less human interference. *Chloris inflata* is found in areas with moist soil conditions, and *Cyrtococcum trigonum* is spread out on the floors of forested landscapes (Pemadasa, 1990). Wild elephants and buffalo are recognized as two species that have a close relationship with this grassland ecosystem, and their grazing helps to maintain these grasslands (MoMD&E, 2019). The *villu* ecosystems (Fig. 10) that dot the landscape in the northwest and along the lower reaches of the Mahaweli River in the northeastern regions of Sri Lanka are also examples of these dry lowland grassland habitats. The *villu* are a reference to the shallow humus-rich depressions that collect rain or flood waters and form isolated wetlands that provide important water sources for wildlife. The *villu* vegetation is dominated by species such as *Iseilema laxum*, *Paspalidium flavidum* and *Fimbrystili* spp. (Pemadasa, 1990).
- Arid pastures are found along the northwestern and southeastern coasts, in Sri Lanka's arid zones, where annual rainfall is less than 1000 mm, interspersed with prolonged droughts. Despite the hostile climate, these are important grazing grounds for both domestic livestock and wildlife. The sandy and muddy flats of Hambantatota and Yala in the southeast and Puttalam and Mannar in the northwest are examples of these arid pastures. The floristic composition is characterized by grasses such as *Cynodon dactylon*, *Eragrostis tenella*, *Zoysia matrella* and the tree species *Acacia eburnean*, *A. planifrons* and *Salvadora persica*.

Other Grasslands of South Asia

In addition to the larger patches—now mostly remnants—of grasslands there are other, less extensive areas of grasslands that occur elsewhere in the Indian subcontinent (Chandran, 2015). These include the grasslands along the Eastern Ghats mountain range, which run parallel to the eastern coast of the Deccan Plateau. These grasslands are drier and occur at lower elevations of around 700 m in the Shevroy hills of Yercaud, Javadi hills and Malkanagiri. The vegetation communities are dominated by species such as *Arundinella setosa* in the higher elevations and *Aristida adscensionis*, *Heteropogon contortus*, and species of *Sporobolus*, *Themeda*, *Chrysopogon* in the lower elevations.

The northeastern hill States of India support several grasslands that are characterized by a unique species community represented by floral elements from the Himalayan region, Southeast Asia, and peninsular India. These grasslands occur in Dzukou Valley in

Fig. 10 The villu grasslands that dot the dry forest landscape of Sri Lanka's dry zone are created around the shallow, humus-rich depressions that collect rainwater and form saucer-like wetlands. As the water evaporates the grasses emerge around the peripheral areas, and form important grazing grounds for the large herbivores, such as spotted deer (*Axis axis*) and Asian elephants (*Elephas maximus*). Courtesy: Devaka Seneviratne.

Nagaland and Manipur, the Ukhrul grasslands of Manipur, Saramati grasslands of Nagaland, and the rolling downs of Shillong. These grasslands are dominated by species of *Festuca*, *Bromus*, *Arundinella*, *Agrostis*, *Cyathopus*, *Coix*, *Tripsacum*, *Cymbopogon*, *Themeda*, *Microstegium*, *Glyceria*, and *Gymnopogon*. The lower hill slopes are also rich in species of *Microstegium*, *Erianthus*, *Narenga fallax*, *Thysanolaena maxima* and several montane bamboos (Chandran, 2015).

The Central Highlands of the Indian Peninsular support grasslands that are interspersed among tropical dry deciduous forests, grow on the rocky patches, and in sparse, open forests. The vegetation is generally comprised of *Manisuris forficulata*, species of *Arthraxon*, *Pennisetum*, *Diectomis*, *Schizachyrium*, *Cymbopogon*, *Themeda*, *Eragrostis* and *Dimeria*. Further south in the Deccan Plateau, the scattered grasslands are dominated by *Sehima nervosum*, *Dichanthium annulatum*, *Eremopogon foveolatus*, *Pollinia fimbriata*, and species of *Bothriochloa*, *Cymbopogon*, *Mnesithea*, *Rottboelia*, *Sorghum*, *Triplopogon*, *Dimeria*, and *Eulalia*.

Concluding Remarks

South Asia's grasslands have existed for millions of years and are considered to be sustained as successional disclimax ecosystems by human activities and natural disturbances such as fire, floods and grazing. In this state these ecosystems provide habitats for a range faunal species, including species that are now adapted to these ecosystems and have even evolved into endemic species. However, intensive use for agriculture, livestock grazing, human settlement, and invasion by exotic invasive species is rapidly changing natural grasslands that will eventually place the survival of grassland adapted species, and the ecosystem services provided by grasslands at risk. Further, shifts in the monsoon seasons, reflected by intense rainfall events and long periods of droughts, are likely to have impacts on the structure and dynamics of grasslands across South Asia (Ratnam et al., 2016).

Finally, it is important to note that the impacts of these various disturbances in driving community and ecosystem dynamics within South Asian grasslands are largely understudied, and the current knowledge of the functional role of herbivores and fires remain mostly limited. Thus, if these important ecosystems are to be sustained, especially under uncertain weather patterns and expanding anthropogenic influences, better understanding of these ecosystems should be gained to formulate effective grassland management strategies.

Abstract

Southern African grasslands occur on mid to high altitudes and originated due to environmental conditions becoming drier and colder towards the end of the Eocene. The cool climatic conditions with incidences of frost together with fire are regarded as one of the most important driving forces that prevent woody species from establishing. The grassland biome of southern Africa comprises close to a third of the total landscape of the region. When compared to other biomes, grasslands have the second highest species richness after the Fynbos biome. The biome contains more than 640 red listed species and provide habitat for a large number of plant and animal species. A total of 34 grass taxa and 67% of the orchid species present in the biome are endemic. The highveld grassland in the north-eastern part of the region contains various centers of diversity with up to 4000 different plant species recorded. Mining, urbanization and agriculture have the greatest negative impact on the total suite of grassland ecosystem services and are responsible for irreversible changes in the biome in terms of species composition and ecosystem functioning. Climate change is expected to impact on the size, structure, and species richness of the area.

History of Southern African Grasslands

In terms of vegetation, grasslands are relative newcomers to the world and only evolved about 30 million years ago ([McCarthy and Rubidge, 2005](#)). Before grasses established the vegetation of the low to moderate rainfall areas of the Earth was characterized by either bare soil patches or small dwarf shrubs. The higher rainfall areas comprised tall forests ([McCarthy and Rubidge, 2005](#)). Southern Africa was characterized by subtropical forests and woodlands (savanna) before climate changes took place that led to the establishment of grassland vegetation ([Bredenkamp et al., 2002](#)). The earliest grasses occurred in the dry areas and competed with dry woodland species ([McCarthy and Rubidge, 2005](#)). Later other grasses became established in wetter and cooler areas. According to [Retallack \(2001\)](#) grasslands played a major role in cooling the environment over the past 30 million years. This is as a result of their relative lighter color compared to woodlands and forests which means they reflect a greater proportion of solar radiation into space. That causes cooler soil temperatures while more water is retained in the soil due to the dense cover of the grassland vegetation. Research has established that grassland vegetation is closely associated with geology, soil, and climate ([Bezuidenhout, 1993](#)).

Southern African grasslands are located at mid to high altitudes (1200–3400 m) and originated due to the environmental conditions becoming drier towards the end of the Eocene as well as the cooler conditions caused by continental uplift. The cooler conditions are regarded as one of the most important driving forces that prevent woody species from establishing ([Bredenkamp et al., 2002](#)). According to [Anderson \(1999\)](#) the climatic change that took place during the Oligocene caused southern Africa to become 5% colder which provided ideal conditions for the establishment of primary grasslands.

What Is the Scope of Southern African Grasslands?

Southern African grasslands form part of the world temperate grassland biome which comprises the steppes of Russia, Mongolia and China, the north American prairies, the South American pampas, temperate grasslands of Australian Alps and the tussock grasslands of New Zealand ([Mucina and Rutherford, 2006](#); [Van As et al., 2012](#)).

When defining the grasslands of southern Africa, the following definition refers: “Herbaceous vegetation dominated by the family Poaceae with various other forb and dwarf woody species in-between.” Grasslands are diverse in terms of species composition and vegetation structure. In terms of species richness there are more individual forb species recorded than individual grass species. In simple terms it is estimated that only one in every six plant species in grassland is a grass species. It is, however, interesting to note that the forb species (short-leaved herbaceous plants and ferns) are mostly inconspicuous due to the dominance of the taller grass species. Grasslands have a relatively high canopy cover and biomass production compared to woodland plant communities (O'Connor and Bredenkamp, 1997). The average annual rainfall of southern African grassland areas ranges between 250 and 900 mm depending on the region. They are mostly associated with wet summer rainfall period followed by a relatively dry winter period. Summer temperatures are warm (up to 38 °C) and the winters cold (sometimes as low as –4 °C) with frost and snow a common occurrence (Van As et al., 2012).

The grassland biome of southern Africa comprises 28% of the land surface and is the second largest biome after the savanna biome (Carbutt et al., 2011). The grasslands occur mostly on the high central plateau (also known as the Highveld region), the mountainous inland areas of KwaZulu-Natal and extends to the central parts of the Eastern Cape Province (Fig. 1) (Mucina and Rutherford, 2006). These include both warm-temperate and cool-temperate grasslands. In the high-lying altitude mountainous areas of the Maluti-Drakensberg range sub-alpine grasslands are present. The warm-temperate grasslands of southern Africa comprise C4-dominated grasses and occurs both under dry and mesic conditions while the high-altitude grasslands are dominated by C3 grasses (Van Oudtshoorn et al., 2011). The latter is rich in endemics and has mountain summit affinities with East African grasslands as well as Fynbos lineages, such as *Ehrharta* spp. (Verdoorn et al., 2003). The grassland biome of southern Africa interfaces with the Nama-karoo biome in the dry western and south-western boundary, indigenous Afromontane forests along its south-eastern boundary and the bushveld and savanna regions in the north. Although smaller grassland patches, referred to as satellite grasslands, do occur within other biomes of southern Africa, they are not considered as belonging to the grassland biome as per the above definition. These satellite patches are part of the natural herbaceous layer of these different biomes. The boundaries between the grasslands and adjacent biomes are not always clearly defined. In most cases the changes from grassland vegetation to that of another biome is gradual with an overlap between species of the two biomes (Van As et al., 2012).

Mucina and Rutherford (2006) has described a total of 72 different grassland vegetation types based on their floristic composition. According to Scholes and Von Maltitz (2015) they can be grouped into five broad categories: Dry Highveld (between 400 and 550 mm of rain), Mesic Highveld (> 550–800 mm of rain), High-Altitude or sub-alpine grasslands on the Drakensberg (> 800–2000 mm of rain), Sub-Escarpment on foothills of the escarpment, and the Coastal grassland.

The grassland biome of southern Africa is also one of the most impacted and as a result, degraded areas of the region (Bezuidenhout, 1993). This is ascribed to the geology, topography soil, and climate that makes these areas suitable for mining, agriculture and urbanization (Brown and Du Preez, 2014).

The grassland biome of southern Africa occurs within South Africa, Lesotho and Swaziland and comprises 46,653,419 ha (Table 1). The largest proportion, 91% (42,553,492 ha) occurs in South Africa with 9% (4,053,122 ha) occurring in Lesotho and 1% (46,805 ha) in Swaziland. The Mesic Grassland vegetation type occurs in all three countries and comprises an area of 15,889,414 ha. The Sub-escarpment Grassland vegetation type is 10,159,429 ha in size and occurs only in Swaziland and South Africa, while the Drakensberg vegetation type occurs only within South Africa and Lesotho and are more or less equal in size comprising 2,873,824 and 2,801,325 ha respectively. The Dry Highveld grassland vegetation type only occurs on the higher-lying escarpment of South Africa on more than 15 million hectares of land.

Ecosystem Modifiers

Various environmental and anthropogenic influences play a significant role in the species composition, richness and structure of the various landscapes of the grassland biome.

Geology, Soil, and Terrain

Geologically the largest part of the grassland biome of southern Africa is located on the Karoo Supergroup which is underlain by the Witwatersrand, Ventersdorp and Transvaal Supergroups. The latter has been deposited during the Archaean period (between 3100 and 2000 million years ago) with the Karoo Supergroup being deposited on top during the Phanerozoic period (60 million years ago) (McCarthy and Rubidge, 2005). Various metamorphic and igneous rocks intruded into sections of the Karoo Supergroup which resulted in the forming of the so-called African super swell. Furthermore, the Limpopo, Kalahari and Karoo river systems were responsible for eroding large sections of the Karoo Supergroup strata giving rise to the higher-lying escarpment areas of the grasslands of southern Africa (McCarthy and Rubidge, 2005; Mucina and Rutherford, 2006).

Within these supergroups some of the most important economically valuable minerals in the world are found. In particular southern African grasslands have the largest gold, manganese and platinum reserves in the world, which is augmented by large deposits of other similarly important commodities such as diamonds, coal and iron ore. Most of these mineral deposits have been the backbone of the region's economic growth for many years (Cairncross, 2004) and have been responsible for various anthropogenic changes in the grassland vegetation in terms of species composition and structure.

Fig. 1 Location of the grassland vegetation of southern Africa. Adapted from Mucina, L. and Rutherford, M.C. (eds.) (2006). *The vegetation of South Africa, Lesotho and Swaziland: Strelitzia 19*. Pretoria: South African National Biodiversity Institute.

Table 1 Sizes of the different grassland types within southern Africa.

Country	Grassland type	Area size (ha)	Total (ha)
Swaziland	Mesic Highveld Grassland	378716	46805
	Sub-Escarpment Grassland	46805	
Lesotho	Mesic Highveld Grassland	1251796	4053122
	Drakensberg Grassland	2801325	
South Africa	Mesic Highveld Grassland	14258902	42553492
	Dry Highveld Grassland	15308142	
	Sub-Escarpment Grassland	10112624	
	Drakensberg Grassland	2873824	
	Total		46653419

In terms of topography and soil the area consists of relatively large homogeneous landscapes. Most of the grassland biomes' in situ soil forming has caused differences in inorganic nutrients in the soil throughout the biome. The soil nutrient content is delimited by soil depth, texture, and rainfall (Hillel, 1971). Weathering of the rocks caused by wind and water erosion has given rise to various Land Types, Terrain Units, and Soil Forms (Soil Classification Work Group, 1991; Land Type Survey Staff, 1986).

Fire

The grassland biome of southern Africa has a high lightning strike density making the incidence of fires a regular occurrence in these ecosystems (Mucina and Rutherford, 2006). According to O'Connor and Bredenkamp (1997) fire is vital in the maintenance of the structural and specific species composition of grassland areas. Although fires are naturally caused by lightning strikes and, in rare instances, by rock falls (Van As et al., 2012), anthropogenic fires have become more prevalent in southern Africa. Fire plays an important role in maintaining the grassland structure and species composition. According to Midgley et al. (1997) regular fires in grasslands are regarded as the main cause of abrupt boundaries between grassland and forest since it inhibits the establishment of seedlings of woody species in the grassland areas (Fig. 2).

Natural fires occur mostly from late winter to early spring within the summer rainfall areas. The fire intensity is dependent on the amount of fuel available, the fuel moisture, air temperature and wind speed (Mucina and Rutherford, 2006). Fire is in most cases beneficial to the ecosystem and the plants and wildlife occurring in fire prone areas are adapted to these conditions. Fire can have direct or indirect impact on vegetation and wildlife. Direct impacts depend on the type of plant species and organism. In cases where the plant species and/or wildlife is not adapted to fire, they will in all likelihood be killed (Van As et al., 2012). Where grasses are not regularly defoliated by grazers it could lead to the vegetation becoming moribund. In such a case the fire removes all moribund material and stimulates the growth of the vegetation (Trollope, 1999). When fire removes vegetation cover more light is available that stimulate grassland geophytes to grow and flower before the grasses resprout or recover. Regular fire in grasslands also kill seedlings of woody plants encroaching into these areas thereby maintaining the grassland species composition (Van As et al., 2012).

**Fig. 2** Normal surface fire within the grassland vegetation of southern Africa. Photo: LR Brown.

The incorrect use of fire could cause ecosystem degradation that results in a loss of plant species, erosion, decreased water infiltration as well as woody species encroachment.

In southern Africa fire is used effectively as a management tool in natural areas as well as cultivated grasslands to maintain and/or enhance grazing (Trollope, 1999). One of the most common practices of fire in land management is to use fires regularly to prevent accumulation of dry material that could cause high intensity wild fires (Whelan, 2002).

Climate

Grasses are well adapted to withstand cold temperatures as well as overgrazing. That is due to their meristematic tissues being located close to the ground level. Grasses are furthermore dormant during the dry winter season which allows them to withstand frost and even snow. In contrast broad-leaved savanna woody species are not adapted to the longer periods of extreme cold temperatures and can therefore not establish in these areas.

Different grass plant species grow during different times of the growing season. The dominance of the grass species in a specific grassland community is influenced by the season and the amount of rainfall received (Bezuidenhout et al., 2018). Grasslands are regarded as event-driven resilient ecosystems. During drought times or as a result of overgrazing the grass biomass is greatly reduced resulting in a greater visibility of perennial forbs and dwarf shrubs. However, during high rainfall events the grass layer recovers rapidly with a significant increase in biomass and less visibility of the perennial forbs and dwarf shrubs.

In the sub-alpine grasslands at high altitudes, the cold temperatures and shallow high clay content basalt derived soil results in grasses having a stunted bonsai-like growth form.

Southern Africa does not have cold resistant trees that can withstand continued low temperatures and incidences of frost as found in the northern hemisphere. Very few savanna species have developed a tolerance to cold, dry conditions and frost that is prevalent in the grassland biome of southern Africa. Only woody species that have developed a tolerance to cold conditions are found scattered in some grassland sections. One such species, the tree *Vachellia karroo*, is regarded as a forerunner in the woody encroachment of grassland areas especially where overgrazing has taken place (Bredenkamp et al., 2002).

Thus, cold temperatures and fire are important ecosystem modifiers responsible for the maintenance of the structure and species composition of grasslands.

Grazing

Grasses are well adapted to being defoliated due to their meristematic tissues being located at the base of the leaf. That means that if the aboveground leaf material of young leaves is removed the plant will continue to produce new leaf material. According to Bredenkamp et al. (2002) the establishment of grasses together with grazers is a remarkable case of symbiotic co-evolution. Grazing of grasslands affect the plant species composition and production of the grass plant. Koerner and Collins (2014) found that grazing of grasslands increased diversity while decreasing grass cover. They also found that both the production and below ground biomass decreased as a result of grazing. The effect of leaf removal of the grass is dependent on the amount and parts of the leaf removed (Wolfson, 1999). The removal of part or the whole leaf will reduce the photosynthetic capacity of the grass that could result in lower production. However, if the grasses are moderately grazed it will lead to a compensatory increase in photosynthetic efficiency in the remaining leaves (and culms) that would not significantly reduce the production of the grass (Wolfson, 1999). Thus, there is mostly a temporary and short-term decline in photosynthetic capacity and production under normal grazing conditions. De Klerk et al. (2001) estimate that grazed areas might only achieve the same production of non-grazed areas after 4 years of normal grazing. According to O'Connor (2005) the stocking rate of livestock and wildlife in grassland areas are currently 6–20 times higher than before humans settled in these areas. This is one of the main reasons for the decline in grass production and change in species composition of grassland vegetation in southern Africa. Overgrazed grassland areas are also prone to woody species encroachment which not only causes a shift in species composition, vegetation structure, but also a loss in valuable grazing land. Grazing is, however, a natural phenomenon of healthy grassland ecosystems in order to maintain the vitality of the grass plants. If a grass is not moderately defoliated on a regular basis, it could lead to the grass becoming moribund and eventual death of the plant. Therefore, properly planned and executed grazing strategies will maintain the grassland ecosystem patterns and processes.

Biodiversity

The term biodiversity refers to the diversity and number of viable plant and animal species present in an area (Brown and Du Preez, 2014). The grassland biome of southern Africa contains a variety of aesthetically pleasing landscapes with a high biodiversity value. According to Cowling et al. (1989) data on plant species richness and diversity for the total grassland biome of southern Africa is not readily available. Between 9 and 29 plant species have been recorded in 100 m² vegetation sample plots within high-altitude grasslands of the Eastern Cape and KwaZulu-Natal (Eckhardt et al., 1996). According to Van Oudtshoorn (2008) it is estimated that southern African grasslands contain between 55 and 100 species per 1000 m². According to Siebert (2011) southern African grasslands has a mean plant species richness of 61 species per 100 m². Cowling et al. (1989) found that grasslands have a high alpha diversity and a moderate gamma diversity with the highveld grassland region containing various centers of diversity with up to 4000 different plant species recorded in this area. When compared to other biomes in southern Africa, grasslands have the second highest

Table 2 Mean species richness per 1000 m² for selected biomes of southern Africa.

<i>Biome</i>	<i>Number of species</i>
Fynbos	86
Grassland	82
Succulent karoo	74
Forest	51
Nama karoo	47

Adapted from Van Wyk, A.E. (1998). *Grassland: The most threatened Biome in South Africa*. Pretoria: Unpublished report.

species richness after the Fynbos biome (Table 2). The grassland biome of southern Africa contains more than 640 red listed species of which 136 are threatened by extinction while six are already extinct. Of these red listed species only nine are grass species (Mucina and Rutherford, 2006). A total of 34 grass taxa are endemic to the southern African grasslands (Steenkamp et al., 2002). In addition, Linder et al. (2005) states that of the 161 orchid species found within the grassland biome, a total of 67% are endemic.

In terms of animal species, the grassland biome provides suitable habitat for ungulates, birds, insects, and amphibians.

Ecosystem Services

Apart from providing valuable grazing to wildlife, southern African grasslands play an important role in terms of water production, purification and retention in this water scarce region (O'Connor, 2005). Egoh et al. (2011) state that grasslands also provide ecosystem services in terms of soil conservation and carbon storage. Grasslands effectively remove carbon from the atmosphere and where woody species store the carbon in their organs, grasses store it in the soil. Thus, the grassland soils are far richer in carbon than forest soils (McCarthy and Rubidge, 2005). This can be partially ascribed to regular fires in grasslands that result in a large number of carbon rich ash being produced. This carbon rich ash is not easily decomposed by soil bacteria and therefore contributes to the higher carbon concentrations in grassland soil (McCarthy and Rubidge, 2005). Other ecosystem services include forage production, medicinal resources, biodiversity, erosion regulation, tourism, bird-watching, and hunting. According to Scholes and Von Maltitz (2015) it is estimated that the value of the ecosystem services from grassland is in excess of \$650 million.

Threats to the Grasslands of Southern Africa

Urbanization, agriculture, rural settlements, and mining have had the most severe negative impacts on the biodiversity of grassland ecosystems (O'Connor and Kuyler, 2009; Cilliers et al., 2004). The largest areas affected by urbanization include the Johannesburg-Pretoria region in the northern parts of the biome as well as the eastern and central parts of the biome (Fig. 3). Urbanization causes the establishment of impermeable surfaces, landscape fragmentation, habitat loss and a loss in natural resource pathways and biodiversity (Van der Walt et al., 2015).

Most grassland areas are prime land for agricultural practices such as grazing and planting of crops (Fig. 4). The largest concentration of agricultural practices is conducted within the grassland biome. Compared to the rest of southern Africa the grassland biome is the most impacted and therefore under threat (Fig. 3). The planting of crops results in the total destruction of the natural vegetation and alters the soil profile, while the long-term application of fertilizers and herbicides has a negative effect on the soil nutrients and micro-organisms of the system.

Overutilization in terms of grazing combined with the effect of trampling degrades the grassland habitat making it susceptible for invasion by alien plants and woody species encroachment. Thus, incorrect grazing practices and stocking rates combined with drought events can alter the structure, composition and ecosystem functioning of the grassland areas. Moderate to heavy grazing by domestic animals causes a decrease in forb species richness of up to 84% and even leads to the extirpation of certain perennial forbs (Scott-Shaw and Morris, 2014). In areas where land is left fallow it seldom if ever returns to its original vegetation structure. Breidenkamp and Brown (2003) found that natural grasslands in the Highveld region of South Africa that are degraded due to anthropogenic influences become dominated by thatch grasses (*Hyparrhenia* spp.). These *Hyparrhenia*-dominated grasslands tend to be stable for a very long time (up to 50 years or more) and mostly have low species richness and diversity. In the high-altitude sub-alpine grasslands of Lesotho uncontrolled and ill-managed grazing programs have resulted in the degradation of the grasslands as well as its associated peatlands where large-scale erosion occurs. This has negative impacts on the larger and very important water catchment that is regarded as the most important water catchment area of southern Africa (Du Preez and Brown, 2011).

The mining of the significant mineral deposits and urbanization contribute to the continued degradation of the ecosystem (Bezuidenhout 1993). More than 40% of the country's mining activities are located in this biome (Scholes and Von Maltitz, 2015) (Fig. 5). Various coal, diamond, gold and bentonite mining activities to name a few occur throughout the grassland biome

Fig. 3 Urbanization within the grassland biome compared to the rest of the region (no data is available for the country of Lesotho and is therefore not indicated in the figure).

Fig. 4 Agricultural practices within the grassland biome compared to the rest of southern Africa (no data is available for the countries of Lesotho and Swaziland and is therefore not indicated in the figure).

Fig. 5 Mining activities within the grassland biome compared to the rest of southern Africa (no data is available for the countries of Lesotho and Swaziland and is therefore not indicated in the figure).

(Brown and Du Preez, 2014). These activities normally result in the total destruction of the natural ecosystem and cause a loss of natural grasslands. In order to prevent the large-scale loss of these ecosystems current government legislation requires mining companies to obtain similar natural areas that could be used as offset areas to conserve specific grassland ecosystems (Bull et al., 2013).

The spread of alien invasive plants threatens the diversity and functioning of natural ecosystems worldwide (Van Wilgen et al., 2001). These alien plants have the ability to outcompete the natural grassland vegetation thereby displacing the natural species of the area. That leads to a loss of diversity and habitat for many plant and animal species. Alien plants also use more water than indigenous grass species and contribute to the drying up and degradation of the land (Forsyth et al., 2012).

Incorrect burning strategies, continuous overgrazing and general mismanagement of grasslands results in a loss of vegetation cover and a change in species composition. The consequence of these actions results in larger evapotranspiration and therefore loss of water from these ecosystems (O'Connor, 2005). In addition, the loss of vegetation cover results in a greater surface water runoff and less infiltration that causes large scale erosion and poorer water quality of these landscapes.

Connectivity between different natural landscapes is important to ensure natural ecosystem processes and patterns. The fragmentation of the natural habitat is an important factor that contributes toward the loss of and isolation of vegetation thereby creating smaller natural vegetation patches (Fahrig, 2003). Connectivity between different landscapes in the grassland biome is hampered due to different land use practices such as planting of crops, mining, urbanization, and afforestation. This has had a negative impact on the grassland species composition, richness, and general vegetation structure. The farming practices in southern Africa where fences have been erected to manage the land use has also largely contributed to the loss of connectivity between grassland landscapes and their associated wildlife. Although connectivity measurements have not been widely used in habitat fragmentation determinations in southern Africa, it is gradually gaining momentum as a conservation planning tool (Fourie et al., 2015).

Fuggle and Rabie (1992) developed a matrix whereby the various anticipated impacts of any anthropogenic activity on the ecosystem can be assessed. Table 3 presents an adapted analysis of different threats on the ecosystem services of the grassland biome.

According to Table 3 mining and urbanization have the greatest negative impact on the total suite of grassland ecosystem services. Almost all the impacts of these activities on the ecosystem are highly significant and irreversible. Cultivation activities is the third most significant impact on the grassland ecosystem services with more than 50% of the activities resulting in irreversible changes to the ecosystem. Alien plant invasions have significant negative effects on grassland processes and patterns, as well as water purification and retention. Alien plants are well-known to use more water and lose it through transpiration than indigenous species (Le Maitre et al., 1996). Fragmentation of the grassland environment has negative effects on the grassland processes and patterns while also possibly having a negative effect on climate change. Incorrect management practices are regarded as having significant negative effects on the grassland ecosystem, however if correctly managed and detected early it could be mitigated by implementing correct management strategies. If this is not done it would most probably have the same negative impact as mining and urbanization.

Conservation

Grassland areas are important in terms of plant and wildlife biodiversity as well as a water resource. Large sections of the grassland biome of southern Africa have been degraded or transformed due to human activities (e.g., agriculture, mining, urbanization, overgrazing, etc.). It is estimated that close to 33% of the biome has already been irreversibly transformed primarily as a result of anthropogenic influences (Carbutt et al., 2011). A further 7% has been severely degraded due to soil erosion and poor land management, while it is estimated that 30% of the remaining grassland areas are secondary grasslands on previously degraded areas (Mucina and Rutherford, 2006).

Afforestation of the grassland biome has resulted in the large sections of the grassland being destroyed (Fig. 6). Although this practice is declining with some plantations being terminated, it is of utmost importance that these areas are restored by scientifically defensible and well-informed restoration plans. Degraded (ploughed, overgrazed, mined) grassland areas do not naturally recover to its original climax condition. Whereas the degraded grasslands of western Europe become overgrown by woody species, degraded southern African grasslands remain grass dominated (Bredenkamp et al., 2002) and develop into a species poor grassland normally dominated by secondary successional grasses such as *Hyparrhenia hirta*, *Eragrostis rigidior*, *Hyperthelia dissoluta*, and *Eragrostis curvula* together with a variety of pioneer weedy forbs.

Although sections of the grassland biome are conserved in smaller nature and private reserves, they only account for 2.2% of the grassland biome. Furthermore, not all areas of the biome are equally protected, with the highveld grasslands especially poorly conserved (Low and Rebelo, 1996). Apart from the highveld grassland areas, the northern parts of the grassland biome are characterized by the lack of formally protected conservation areas. According to Zunckel (2003) the establishment of the Maluti-Drakensberg Transfrontier Park which encompass grasslands that are found in Lesotho, KwaZulu-Natal and the Golden Gate Highland National Park is one of the most important grassland biome conservation initiatives in the region. The National Grasslands Biodiversity Programme (NGBP) which aims to ensure sustainable long-term management, research and conservation of the grassland biome, hosted by the South African National Biodiversity Institute (SANBI) is another initiative to protect the grassland biome.

Table 3 An analysis of the different threats on grassland ecosystems in southern Africa (Color coding were given to the different categories based on their significance: *Red*, high; *Orange*, Medium; *Yellow*, Low; *Gray*, undetermined).

Fig. 6 Large areas of the grassland biome have been planted with forest plantations for commercial purposes thereby destroying the natural grassland ecosystem. Photo: LR Brown.

With the advent of anthropogenic climate change it is predicted that the extent of the grassland biome may become reduced by up to 55% with a significant change in plant species composition and vegetation structure. The areas that are most likely to be affected are the north-western portion of the current grassland biome (Mucina and Rutherford, 2006). Changes in abundances and species are predicted to occur with a heightened risk of extinction for many species as a result of climate change (Huntley and Barnard, 2012). The loss of suitable habitat for various animal species (mammals, insects, and birds) could also have far-reaching effects in terms of ecosystem functioning since these species play a role in pollination, seed dispersal, and maintaining general grass vitality.

The grasslands of southern Africa as a result of its ongoing transformation due to the various threats listed above is regarded as one of the most threatened biomes (Scholes and Von Maltitz, 2015). It is imperative that conservation efforts in southern Africa are properly planned and implemented to ensure the long-term functioning of this highly important and diverse biome. The increase in human population in southern Africa together with an increase in management pressures in terms of agricultural and urbanization demands as well as climate change will place more pressure on the natural grassland vegetation and its biodiversity. Biodiversity conservation not only refers to the protection of specific species, but also habitats, ecosystems, and landscapes (Van As et al., 2012). The solutions to the conservation of grasslands will mostly depend on the decisions and actions in the socio-political arena (Watkinson and Ormerod, 2001).

Abstract

Tropical savannas comprise the main environment across the 2 million km² of monsoonal northern Australia. As with savannas world-wide, Australian tropical savanna vegetation is characterized by a dense C₄ grass layer and variably open tree layer. Vegetation structure and composition vary across the gradient of annual rainfall from c. 2000 mm (in the coastal north) to c. 500 mm (inland), with tree cover and height greatest in higher rainfall areas. Unlike most tropical savannas globally, in the Australian tropical savannas, most canopy trees are evergreen, with eucalypts (*Eucalyptus* and *Corymbia* species) dominating. Influenced by a long annual dry season, fire is frequent and is a major influence on vegetation, particularly shaping the extent of a shrubby understorey layer. The fauna is highly distinctive—for some groups it is extremely rich and with high levels of endemism, but it lacks native megaherbivores. The Australian tropical savannas have remained extensive and largely intact, with relatively low human population density, little habitat loss, and no known extinctions over the c. 200 years since European settlement. However, some native species are now declining, many invasive species have become pests or weeds, and there is ongoing pressure to modify habitats to allow more intensive development.

Introduction

Tropical savannas occur in the seasonal tropics of Africa, South America, Asia and Australia. A dense grass layer is a defining feature, but vegetation structure varies from essentially grasslands with sparse trees, especially on cracking-clay soils, to open forests with a mixed understorey of shrubs and grasses, typically on deep sandy loams with high annual rainfall. Australia's tropical savannas occur extensively as the dominant vegetation type across the northern quarter of the continent. Intermixed with the tropical savannas are smaller areas of other biomes, including rainforest patches, treeless floodplains, and heathlands, with the latter occurring on some sandy coastal soils (especially on Queensland's Cape York Peninsula: Fig. 1A) and on skeletal or sandy soils in rugged rocky areas. Here we treat the Australian tropical savannas as a single ecoregion, despite the presence of numerous non-savanna vegetation types.

Biogeography

Australia's tropical savannas occupy about 2 million km² of the north Australian mainland (Fig. 1A) and many nearby islands including three of Australia's largest: Melville (5786 km²), Groote Eylandt (2285 km²) and Bathurst (1693 km²). The southern limit of the tropical savannas is loosely delineated by the limit of strongly seasonal monsoon influence, with gradational shift to the semi-arid and arid environments of inland Australia, down to mean annual rainfall of about 250–500 mm. In the wet tropics of North Queensland, the savannas abut tropical rainforest, and small patches of rainforest are embedded in tropical savanna throughout northern Australia, especially along rivers and creeks and around permanent springs.

Similar environments, with many shared plant and animal species, also occur in the Trans-Fly area of southern New Guinea, which was connected to Australia during periods of lower sea levels in the Pleistocene (Nix and Kalma, 1972), as well as in most of Timor and elsewhere in eastern Indonesia, outside the Australian continent.

The Australian tropical savannas extend largely uninterrupted across an east–west arc of about 3000 km (Fig. 1A). Given this continuity, many plant and animal species occur throughout this environment. However, there are some notable landscape breaks and barriers that have served as variably effective evolutionary divides (Potter et al., 2012). Areas of rugged terrain in the Kimberley, the Arnhem Plateau in the Northern Territory and parts of Cape York Peninsula have a long history of differentiation from the lowland environments, and harbor many species that are either endemic or with relictual distributions (Woinarski et al., 2009).

Fig. 1 (A) The extent of the tropical savannas in northern Australia (Fox et al., 2001), across three states, with (B) mean annual rainfall (modified by authors from data held by Australian Bureau of Meteorology), (C) the proportion of mean annual rainfall that falls during the summer months (December–February, inclusive) (modified by authors from data held by Australian Bureau of Meteorology), (D) tree cover, based on MODIS satellite imagery (Hansen et al., 2003); and (E) annual fire frequency, based on the MODIS satellite record (2000–2017) (Giglio et al., 2016). The dashed lines indicate the Tropic of Capricorn.

Vegetation and Environmental Setting

The Australian tropical savannas comprise a range of open forests, woodlands and open woodlands dominated by eucalypts (i.e. trees from the closely related genera *Eucalyptus* and *Corymbia*) over an understorey of C_4 grasses. The two most widespread and dominant eucalypt species are Darwin stringybark (*Eucalyptus tetrodonta*) and Darwin woollybutt (*E. miniata*), especially in savannas with mean annual rainfall exceeding 700–800 mm. The most common non-eucalypt overstorey species is the legume Cooktown ironwood (*Erythrophleum chlorostachys*), which also occurs across the savanna zone where annual rainfall exceeds 700 mm. Beneath the eucalypt-dominated canopy, a range of non-eucalypt species may form a conspicuous midstorey. These tend to be from pantropical genera such as *Terminalia*, *Buchanania* and *Planchonella*. While the overstorey eucalypts are typically evergreen, many of the midstorey species are deciduous. The Australian tropical savannas are exceptional in the dominance of evergreen trees despite extreme rainfall seasonality. The overstorey eucalypts are also remarkable in their extreme fire tolerance, with juvenile eucalypts able to survive repeated burning, and grow rapidly to fire-resistant sizes between fires. Non-eucalypt species of the midstorey tend to be more fire-sensitive, and often only persist in frequently burnt savannas as suppressed juveniles in the understorey. Remarkably, many non-eucalypt species of the midstorey are able to complete their life cycle (i.e. flowering and fruiting) while suppressed, effectively living as shrubs, within the flame zone. A conspicuous component of the upper understorey to lower midstorey of many eucalypt open forests and woodlands are arborescent species such as sand palms (*Livistona* spp.) and cycads (*Cycas* spp.). The understorey of the Australian tropical savannas is a variable mix of C_4 grasses and shrubs, mainly depending on tree cover. Typically, as tree cover increases, grass biomass decreases, given the shade-intolerance of C_4 grasses.

The structure and floristic of Australian tropical savannas are strongly influenced by a strong north–south rainfall gradient, from about 1800 mm annually at the most northern coastal regions, to 250 mm annually in western Queensland (Fig. 1B). The mesic coastal savannas of the north have higher tree biomass, higher tree densities, larger trees (especially in terms of tree height), and greater canopy cover, compared to the arid savannas of the south (Fig. 2). Like savanna regions elsewhere, the climate of the Australian tropical savannas is characterized by intense rainfall seasonality, with the vast majority of rainfall falling in the summer monsoon months (Fig. 1C), typically December to April. The length and intensity of the dry season promotes high frequencies of fires. In the long-term absence of fire, much of the higher-rainfall savannas experience an increase in tree density sufficient to exclude C_4 grasses and switch to non-savanna biomes, such as dry forests—although the long-term absence of fire is exceptionally rare in natural settings.

Fig. 2 Variation in savanna structure with decreasing mean annual rainfall in the Northern Territory. Panel (A) is near the north coast, near Darwin, and (E) is about 600 km south, near the southern, arid margin of the tropical savannas. (A) Darwin: 1700 mm. (B) Southern Kakadu: 1320 mm. (C) Mataranka: 950 mm. (D) Maryfield: 800 mm. (E) Newcastle Waters: 550 mm. (A) Photo by John Woinarski. (B–E) Photo by Alan Andersen.

In addition to climate, soils and topography exert strong control over the tree stand structure of the tropical savannas. Deep soils tend to hold more water, especially throughout the dry season, and typically support higher tree basal area, and taller trees. Skeletal soils, such as on sandstone plateaux, support very low tree basal area. In such areas, savanna woodlands grade into heathlands. Hence, the general positive relationship between mean annual rainfall and tree abundance (e.g. basal area, canopy cover; Fig. 2) tends to be highly variable.

Within the broad savanna matrix (Fig. 1A), there are a number of more-restricted non-savanna biomes, including: seasonally inundated treeless floodplains; swamps, including seasonally flooded *Melaleuca* forests; rainforest patches, both evergreen and deciduous; and heathlands. Extensive treeless floodplains occur adjacent to many large rivers in coastal areas, and support a range of grass and sedge species. Floodplains and rivers are often fringed by *Melaleuca* swamps and riparian forests. Heathlands predominantly occur on rocky, sandstone landforms, where the skeletal, infertile soils prevent the development of a tree canopy. The largest areas of sandstone heathland are on the Arnhem Plateau in the Northern Territory and in the Kimberley, Western Australia (Fig. 1A), with high levels of plant endemism and species richness of fire-sensitive shrub species. The tropical sandstone heathlands have floristic similarities with southern Australian heathlands, including diverse shrubs of the families Myrtaceae, Proteaceae and Fabaceae.

Fauna

Australia's tropical savanna fauna is highly distinctive and—for at least some groups—extremely rich and with high levels of endemism. They are home to about 75 frog species of which about 50 are endemic to the area, 400 reptiles (240 endemic), 340 birds (excluding marine species and occasional visitors, and including about 30 endemic species) and 135 mammals (60 endemic). Local vertebrate richness can be high: for example, the c. 20,000 km² Kakadu National Park supports about 140 reptile and 65 mammal species. Even the vertebrate fauna is far from comprehensively known, with many recent studies, especially those incorporating genetic analysis, substantially adding to the known species tally and discovering hitherto unrecognized local-scale endemism, especially for reptiles.

Diversity and endemism are particularly high in the invertebrate fauna. The best-known groups taxonomically are butterflies (132 species) and day-flying moths (31 species; Braby et al., 2019). Levels of endemism in these groups are relatively low (10%) at the species level, but this figure rises to 31% if sub-species are considered. The ecologically dominant faunal group in terms of biomass and energy flow are ants, which are poorly known taxonomically but their diversity and distribution have been extensively studied (Andersen, 2000). Australian savannas support some of the world's richest known ant faunas, rivaling those of the Amazon Basin. More than 1500 species are likely to occur in the savanna environments of the Northern Territory alone (Fig. 1A), with 60% of these occurring nowhere else (Andersen et al., 2018). Levels of ant diversity and endemism are similarly high in the Kimberley, and this is also very likely the case on Cape York Peninsula. Other important insect groups are termites and grasshoppers, but their levels of diversity and endemism have been poorly documented.

The Australian savanna fauna has dichotomous biogeographic origins, consisting of both autochthonous taxa with Gondwanan heritage and Indomalayan elements that have colonized over the past 20 million years as the Australian continent neared the Sunda Plate. Such a dichotomy is clearest for non-flying mammals, which comprise both marsupials (Gondwanan; about 40 species) and placentals (Indomalayan; about 20 rodent species). Other important Indomalayan elements of the vertebrate fauna include varanid lizards and colubrid snakes. The savanna ant fauna includes many highly diverse genera of Afrotropical/Indomalayan origin, including *Monomorium*, *Meranoplus* and *Tetramorium*, along with dominant autochthonous genera such as *Iridomyrmex* and *Melophorus* (Andersen, 2000).

Assemblages of bird and mammal species and species-groups occurring in the Australian tropical savannas share many similarities with assemblages occurring in the temperate woodlands of eastern and south-western Australia. Many faunal species, including the iconic frilled lizard (*Chlamydosaurus kingii*), agile wallaby (*Notamacropus agilis*) and northern meat ant (*Iridomyrmex sanguineus*), have extensive distributions across Australian savannas. However, many others have highly restricted ranges, often associated with isolated regions of rugged sandstone environments: examples include the rough-scaled python (*Morelia carinata*) and black grass-wren (*Amytornis housei*) from the Kimberley, and the black wallaroo (*Osphranter bernardus*) and very large Oenpelli python (*Simalia oenpelliensis*) from the Arnhem Plateau.

For most faunal groups in Australian savannas, richness and total abundance decreases from areas of higher to lower rainfall (Woinarski et al., 1999). Ants are a notable exception, with very high diversity maintained throughout the rainfall gradient (Andersen et al., 2015). Faunal composition varies with climate, soils, topography, disturbance history and vegetation structure within tropical savanna environments. The most marked contrasts are between treeless grasslands and open forest savannas. The grasslands at the low-rainfall inland edge of the savannas have a distinctive fauna, with characteristic species including the flock bronzewing (*Phaps histrionica*)—a highly nomadic species occasionally occurring (albeit mostly formerly) in immense flocks—and Spencer's monitor (*Varanus spenceri*), one of Australia's largest lizards. Typical of grassy environments world-wide, granivorous birds (comprising many species of pigeons, doves and finches, including the spectacular Gouldian finch [*Erythrura gouldiae*]), are a major component of the vertebrate fauna in Australia's tropical savannas, especially in open woodland savannas in relatively low rainfall areas. Many vertebrate species occur only in those savanna environments with greater tree density and height. This is particularly so for hollow-dependent species (such as cockatoos, kookaburras, owls, possums, tree-rats, tree frogs and some monitor lizards), which comprise about 25% of the terrestrial vertebrate fauna of Australia's tropical savannas, with another c. 20% being occasional

users of hollows (Taylor et al., 2003). In contrast to their relatively rich floristic diversity, the small areas of heathlands scattered across the Australian tropical savannas have relatively few vertebrate species associated with them, although a small set of highly restricted grass-wrens occur in heathland and hummock grassland environments in the Kimberley (black grass-wren [*Amytornis housei*]), western Arnhem Land (white-throated grass-wren [*A. woodwardi*]) and the Gulf hinterland (Capentarian grass-wren [*A. dorotheae*]).

Most other tropical savannas in the world, and particularly in Africa, have diverse assemblages of large mammalian herbivores and associated predators. In contrast, the largest extant native mammals of the Australian tropical savannas are a small number of kangaroo and wallaby species, all < 50 kg in body mass. These typically occur at low densities and have relatively low biomass. The largest predator is the dingo (*Canis dingo*/*C. familiaris*) at about 15 kg, which was introduced by IndoMalayan people about 4000 years ago. A diverse suit of megafauna was present in the Australia tropical savannas until the Late Pleistocene. The cause of their extinction is controversial, but most likely due to overhunting by humans, natural climate change, or a combination of both.

The tropical savannas of northern Australia are highly seasonal environments, and animal species respond in diverse ways to this marked temporal change in climate and resource availability. Many disperse widely across savanna environments, tracking spatial and temporal variation in food availability. Others, such as the channel-billed cuckoo (*Scythrops novaehollandiae*) and eastern koel (*Eudynamis orientalis*), are long-distance migrants whose occurrence in Australia's tropical savannas is largely restricted to the wet season, when the resources on which they primarily feed are most abundant. Many other species have very well-defined breeding seasons, timing their reproductive output to match the climate-influenced variation in resource availability.

Land Use and Human Population

Northern Australia has been occupied by humans for at least 65,000 years (Clarkson et al., 2017), and the present-day landscape owes much to this continuous occupation and management, particularly to Indigenous fire management. Indigenous people continue to maintain a major presence in the area, owning much of the land and maintaining responsibility for fire management across large swathes of it.

European settlement of the area began in the 19th Century, with military and trading outposts, for mining and for extensive pastoralism, with the latter land use in particular resulting in the usurpation of Indigenous land ownership across extensive areas. However, in notable contrast to the tropical savannas of other continents, the northern Australian landscape remains sparsely populated. Outside the few major towns, human population density is very low: more than 99% of the tropical savannas has a population density less than 0.1 person km⁻², and the total population in the region is about 620,000.

In contrast to the rest of the savanna world, there is—to date—very little intensive agricultural development in Australian tropical savannas, and consequently only a tiny proportion (c. 1%) of the landscape has been cleared. Pastoralism continues to be the major land use, occupying about 70% of the land area (Fig. 3). Conservation reserves occupy about 16%, with the majority of this reserved area comprising Indigenous Protected Areas, a tenure of rapidly increasing extent in which Aboriginal land-owners enter formal contracts with the Australian government to manage the cultural and natural values of their lands. The establishment of these Indigenous Protected Areas and their associated Indigenous ranger groups has led to some notable improvements in conservation management, and to health, education, and employment outcomes in otherwise impoverished remote communities. Other Indigenous landholdings comprise about 8% of northern Australia.

Fig. 3 Major land uses of the tropical savannas in northern Australia. Conservation reserves include Indigenous Protected Areas.

Incidence and Impacts of Fire

Tropical savanna is the most fire-prone biome on Earth, and northern Australia's savannas landscapes burn with extremely high frequencies. High fire frequencies are driven by the annual cycle of high summer rainfall (Fig. 1B)—which fuels rapid grass growth—followed by an intense dry season—when the grass dries out. Although humans are now the primary source of ignitions of fires in the savannas, even in the absence of humans there is an ample supply of ignitions due to the frequency of lightning storms at the end of the dry season, when the moisture content of grasses is low. Fire frequency is highest in the high-rainfall coastal regions of the monsoon tropics (Fig. 1B and E)—in such regions, typical intervals between fires can be as low as 1–2 years. Moving south into the more arid parts of the tropical savannas, fire frequency declines, driven by declining grass production. In the more arid savannas, fire activity is more temporally variable, following a 'boom–bust' cycle. In these areas, extensive fires occur when fuel has accumulated to sufficient levels to carry fire, especially after high rainfall associated with La Niña events.

Fire has shaped the Australian biota for at least 40–60 million years, long before the development of the northern Australia monsoon, and hence the tropical savannas, over the last 10 million years. Plants and animals of the Australia's tropical savannas possess an incredible diversity of adaptations to cope with frequent fire, attesting to the importance of fire as an evolutionary force in this region. For most species, populations are able to quickly recover after fire, given either high survival rates (especially for vertebrate animals and woody plants), or high post-fire recruitment (especially for herbaceous plants and shorter-lived woody plants). Fire-sensitive species and communities—especially those that are sensitive to short intervals between fires—tend to be concentrated in isolated, fire-protected areas, such as rugged, rocky landforms (e.g. sandstone heathlands, rainforests) or on islands and peninsulas (coastal vine thickets).

Fire in northern Australia has been intensively managed by humans for millennia. Australian Aborigines have traditionally used landscape fire for a wide range of purposes, including hunting and maintenance of forage for game, as well as protection of fire-sensitive plant resources (e.g. yams). The extent to which Aboriginal people deliberately used landscape fire to manage resources led to the coining of the term 'fire-stick farming'. The dispossession of Aboriginal people of their lands in the 19th and 20th Centuries led to a widespread breakdown of traditional fire management across most of northern Australia. It is widely believed that the loss of traditional fire management has led to a significant increase in the frequency of large, intense wildfires, typically late in the dry season when fire weather conditions are most severe, across the tropical savannas.

The loss of traditional fire management, and resultant increase in the frequency of high-intensity fires, is likely to have led to the decline of a number of fire-sensitive plant and animal species, as well as some plant communities embedded within the savanna matrix. Most notably, frequent high-intensity fires are thought to be contributing to the decline of small mammals and a range of granivorous birds, although compelling evidence is limited. Frequent high-intensity fires have driven the widespread decline of the native tree, northern cypress-pine (*Callitris intratropica*), especially in lowland savannas. Plant communities within the savanna matrix listed by the Australian Government as Endangered, with the key threat being frequent high-intensity fires, include the sandstone heathlands of the Arnhem Plateau and coastal vine thickets of the Dampier Peninsula in the Kimberley.

In recent decades, there has been an increasing use of extensive prescribed burning (i.e. the deliberate lighting of fires under relatively mild fire weather conditions) to reinstate more benign fire regimes, typical of those that prevailed under traditional Aboriginal management. In particular, prescribed burning is applied with the intention of shifting the predominant season of fire to the early dry season when fire weather conditions are less severe, so that the resultant fires are less intense, as well as smaller and patchier. Such fire regimes are widely *perceived* as being more conducive to the maintenance of biodiversity, although some researchers have argued that a greater emphasis on reducing overall fire frequencies, and increasing the extent of longer-unburnt areas, is required.

Threats, Conservation Challenges and Management

Due to low human population density and little intensive agricultural development, the tropical savannas of northern Australia have survived as one of the world's most intact extensive natural ecosystems (Woinarski et al., 2007). The total extent of habitat loss is relatively minor (only 1% has been cleared), the conservation reserve system is extensive and reasonably comprehensive (comprising 16% of land area) and, in contrast to most of Australia, no endemic species are known to have become extinct since European settlement about 200 years ago. Furthermore, Australia's tropical savanna environments have retained many vertebrate species and species-groups that have been lost from elsewhere in the continent, including, for example, the rabbit-rats (*Conilurus* spp.), nail-tailed wallabies (*Onychogalea* spp.) and magpie goose (*Anseranas semipalmata*).

However, there are some substantial conservation challenges. Over the last c. 100 years, there have been extirpations of many native mammal species from many locations within the tropical savannas, especially in lower rainfall areas, and severe and rapid losses of native mammals continue, even in the most significant conservation reserves. Although causality remains difficult to circumscribe, much of this ongoing decline is likely to be due to predation by feral domestic cats (*Felis catus*), habitat degradation due to cattle and feral herbivores, and changed fire regimes (Ziembicki et al., 2015); and recent targeted management of these factors has led to some recovery of at least some species in some areas (Legge et al., 2019).

Many introduced species are now widespread and abundant and exert major pressures on native species: in most areas of the tropical savannas, the biomass of introduced vertebrates (especially livestock) now far exceeds that of native vertebrate species (Woinarski, 2014), and high densities of introduced herbivores are continuing to transform and degrade many environments. The cane toad (*Rhinella marina*) was introduced in the 1930s to north-eastern Australia, and has subsequently expanded its range across most of Australia's tropical savannas. The toad has toxins that kill a range of native species that prey on it, and its continuing spread has precipitated severe declines of the northern quoll (*Dasyurus hallucatus*) and many other predators, including snake and goanna (monitor) species. In turn, the marked declines of these previously abundant native predators has destabilized some food webs and led to increases and decreases of many other native species. In much of the tropical savannas, introduced pigs (*Sus scrofa*) are now widespread, and these have become a major threat to many species, including plants, ground-nesting birds and freshwater turtles. Largely because of the pervasive occurrence of introduced species across much of the north Australian mainland, the many islands of northern Australia—that often have not yet been reached by these introduced pests and weeds—are important refuges for many species.

In many areas, the pastoral industry has attempted to increase productivity through the establishment of exotic grasses as forage for cattle. Some of these introduced plants, most notably African gamba grass (*Andropogon gayanus*), have become serious environmental weeds, extending from their initial plantings in pastoral holdings to lands of all tenures (including conservation reserves), out-competing native grasses, fuelling fires that are of far higher intensity and frequency than those typical of native vegetation, and consequently transforming environments from savanna woodlands with a high diversity of native species to a grassland monoculture (Setterfield et al., 2013).

There have been repeated attempts to intensify the resource use and development of Australia's tropical savannas, especially for mining, horticulture and more intensive pastoralism (Cook, 2009). The momentum for development is strong, although often not tempered by the capacity and constraints of the environment or by the risks to the region's natural assets. Consequently, the pace of loss and degradation of native environments (and the biodiversity dependent upon them) is likely to increase.

Australia is the only country to include emissions from wildfires in its national greenhouse gas accounts, and most of such emissions come from savanna burning. This has led to the emergence of a new land-use and economy in savannas that is unique to Australia: a carbon market has been established to trade in reductions in greenhouse gas emissions through prescribed burning in the early dry season that reduces the overall extent of fire and particularly that of higher-intensity fires later in the dry season (Russell-Smith et al., 2013). This has been of particular benefit to remote, economically disadvantaged Aboriginal communities, promoting cultural connection to traditional lands along with employment opportunities and improved health and education. It has also led to the more-purposeful management of fire, a major factor affecting savanna biodiversity. A significant proportion of the high-rainfall (≥ 1000 mm) tropical savannas, mostly Aboriginal lands, are now managed as part of fire/carbon abatement projects. There remains some uncertainty about the extent of overlap between fire regimes managed for the carbon market and optimal fire regimes for biodiversity, although there is likely to be considerable convergence.

Abstract

South-eastern Australian grassy ecosystems include a variety of grassland, grassy woodland and related vegetation types. Prior to European settlement, grassy ecosystems existed in a mosaic, alongside extensive forests and other vegetation types. Some fauna species of grassy ecosystems are distinctive. Australian grassy ecosystems have a history of land-use by Aboriginal

peoples. Since European colonization, grassy ecosystems have been adversely impacted upon, including agricultural transformations, infrastructure development and invasion by pest animals and plants. Many grassy communities are now legislatively recognized as endangered. Recognition of native grassy ecosystems by government ecologists and conservation managers has emerged, with grassland and grassy woodland conservation reserves, off-reserve measures and engagement programs established. There is growing public interest, with community organizations and some landholders being particularly active. In the agricultural sector, there is growing application of sustainable use of native grassy systems. The conservation status of these systems remains poor, particularly that of grasslands, and government policies and legislative enforcement lag.

Description of the Ecosystems

South-eastern (SE) Australian grassy ecosystems include a variety of grassland, grassy woodland and related vegetation types, which prior to European settlement existed in a mosaic, alongside extensive forests on the ranges, and lesser areas of heathlands, wetlands and riparian systems (Keith, 2004; Armstrong et al., 2013; Keith and Pellow, 2015). SE Australian grassy ecosystems have been impacted by post-settlement land-uses since colonization, including agricultural transformation and urban and other infrastructure development (Benson, 1994; Gott et al., 2015; Kirkpatrick et al., 1995; Williams and Morgan, 2015). Many are now legislatively recognized as endangered ecological communities (Australian Government, 2006, 2008, 2009a,b,c, 2016, 2019; NSW Government, 2005a, 2011a,b). Greater interest in these communities emerged in the late 1980s with increased efforts to understand them and application of conservation actions (Kirkpatrick et al., 1995; Williams and Morgan, 2015).

Distribution

Grassy ecosystems are widely distributed throughout continental Australia. Here I focus on grassy ecosystems of temperate south-eastern New South Wales (SE NSW), the Australian Capital Territory (ACT), Victoria and Tasmania. The grassy ecosystems of the following bioregions (Environment Australia, 2000) are described: South Eastern Highlands, NSW South Western Slopes, Sydney Basin and South East Corner in NSW, Victorian Midlands, Southern Volcanic Plain and South East Coastal Plain in Victoria, and Ben Lomond, Northern Midlands, Northern Slopes, South East, King, Flinders, Central Highlands and Southern Ranges in Tasmania. On the mainland, the systems merge with related vegetation types at the northern and western boundaries of these regions.

Definitions

SE Australian grasslands are defined as vegetation dominated by grasses, Poaceae, and forbs of various families, with <10% projected tree and shrub cover (Benson, 1996). Lowland grasslands are defined as those occurring at elevations <1200 m (Australian Government, 2016). Grassy woodlands are defined as vegetation composed of well-spaced trees (10–30% projected foliage cover), the trees with single trunks, with canopy depth of individual trees usually greater than the length of the trunks and mature heights >5 m, with a groundlayer predominately grassy, containing a variety of forbs, and with a variable shrub-layer (Howling, 1996).

Major Systems

Temperate grasslands

NSW temperate grasslands occur throughout the South Eastern Highlands bioregion, with minor occurrences in the following neighboring bioregions: NSW South Western Slopes, South East Corner and Sydney Basin Bioregions (Australian Government, 2016). Studies in SE NSW have defined grassland associations or communities, with Armstrong et al. (2013) describing eight communities defined by dominant grass species, their location within the region and association with either topographical position or geological substrates. The Armstrong et al. (2013) grassland communities, including one occurring on ephemeral wetlands, are dominated by grass species in various combinations. Dominant grasses are kangaroo grass (*Themeda triandra*, Figs. 1 and 2) snow grass (*Poa sieberiana*), several wallaby-grasses (*Rytidosperma*) and speargrasses (*Austrostipa*), and with a number of other taxa being prominent, including redgrass (*Bothriochloa macra*), purple wiregrass (*Aristida ramosa*), nine-awn grass (*Enneapogon nigricans*), wind-mill grass (*Chloris truncata*), hairy panic (*Panicum effusum*) and several species of plume grass (*Dichelachne* spp.) and lovegrass (*Eragrostis* spp.). The communities are generally forb-rich in their undisturbed states, with herbaceous species of the families Fabaceae, Orchidaceae, Asparagaceae, Asteraceae, and Anthericaceae well represented, alongside species from numerous other families (Armstrong et al., 2013) (Fig. 3). Regionally restricted grassland communities have species of grasses, forbs and woody plants similarly restricted in their ranges (Armstrong et al., 2013). Sedges and rushes (Cyperaceae, Juncaceae and several minor families) occur locally in moist patches. A grassland community of low-lying sites with poor drainage is dominated by river tussock (*Poa labillardierei*). Trees and shrubs in the following genera occur in low densities: *Eucalyptus*, *Acacia*, *Melicetyus* and *Bursaria*. Low sub-shrubs in Ericaceae and Fabaceae occur (Armstrong et al., 2013).

Additional NSW grassland types are the maritime grasslands occupying either rocky coastal headlands or unconsolidated beach sands (Keith, 2004), with the exposed headland community dominated by *Themeda triandra*. It resembles *T. triandra*-dominated

communities of the adjacent highlands, differing in having a distinctive forb and shrub component characterized by species typical of the Sydney Basin and South East Corner bioregions (NSW Government, 2005a).

In Victoria, temperate grasslands occur predominately on the Volcanic Plain bioregion, with pockets in the Victorian Midlands and South-east Coastal Plain bioregions (Australian Government, 2008). Two ecological sub-types are recognized: plains grassland, containing three associations, and creekline tussock grassland (Australian Government, 2008). These grasslands, like those in NSW, contain *T. triandra*, but differ from NSW grasslands in having a greater occurrence of semi-arid elements, such as *Ptilotus* spp. and a number of species in Chenopodiaceae. Grasslands occupying low-lying sites with poor drainage are dominated by *Poa labillardierei* (Australian Government, 2008), like those in SE NSW.

Lowland grasslands of Tasmania occur principally in the Tasmanian Midlands, Derwent Valley, the east coast and the southeast, with localized areas in the northwest and on islands in Bass Strait, with two variants defined by their dominant grass species (Australian Government, 2009a). Tasmanian grasslands resemble those on the mainland, with drier sites dominated by *T. triandra* and low-lying sites by *P. labillardierei*. Forbs and associated plants resemble those of the mainland, with some semi-arid elements of the western Victorian grasslands co-occurring with species common to those in SE NSW (Kirkpatrick, 1988; Kirkpatrick et al., 1995).

Temperate grassy woodlands

In temperate SE NSW, and ranging beyond the boundaries of the regions covered here, are a set of grassy woodlands typified by trees of various *Eucalyptus* species, and a forb-rich grassy groundlayer (Australian Government, 2006; Keith, 2004). The groundlayer resembles adjacent grassland communities, often having a similar floristic composition, though a number of forb and shrub species only occur or are more common in woodlands and adjacent dry forests (Armstrong et al. 2013).

In SE NSW, several broad woodland types occur (Keith, 2004). In the Sydney Basin and South East Corner bioregions of NSW, woodlands dominated by forest red gum (*Eucalyptus tereticornis*) occupy deep soils of river flats and granite landscapes (Keith, 2004; NSW Government, 2011a). These have groundlayers dominated by *T. triandra*, and, like the sometimes adjacent coastal headland grasslands, have forb and shrub components typical of their bioregions. A similar woodland type occurs on the Gippsland Plains of Victoria (Australian Government, 2009b).

In the NSW South Eastern Highlands, two main grassy woodland types occur. Most widespread, occurring especially in warmer, low-altitude regions, as well as on the NSW South Western Slopes bioregion and beyond, are the so-called box-gum grassy woodlands. Several distinct communities occur (Armstrong et al., 2013; Australian Government, 2006; Keith, 2004), with most co-dominated by yellow box (*Eucalyptus melliodora*) and Blakely's red gum (*E. blakelyi*). A variety of other eucalypts occur, commonly including apple box (*E. bridgesiana*) and candlebark, (*E. rubida*). Additionally, a number of mid-stratum *Acacia* species occur, along with minor occurrences of she-oaks (*Allocasuarina* spp.), kurrajong (*Brachychiton populneus*) and a variety of other midlayer shrubs, including species in Fabaceae, Asteraceae, Pittosporaceae, Ericaceae and Myrtaceae (Armstrong et al., 2013). Woodlands on the NSW South Western Slopes have white box (*E. albens*) as a co-dominant (Australian Government, 2006), and shrubs in Chenopodiaceae occur more frequently, as these woodlands merge with grassy and shrub-dominated woodlands dominated by gray box (*E. microcarpa*) and white cypress-pine (*Callitris glauca*) on the plains in the far west of the region (Keith, 2004).

Occurring in cooler, higher-altitude regions of the SE NSW highlands are woodlands dominated by cold-tolerant eucalypts, including snow gum (*E. pauciflora*, Fig. 4), ribbon gum (*E. viminalis*), swamp gum (*E. ovata*), black sallee (*E. stellulata*), black gum (*E. aggregata*), and *E. rubida* (Keith, 2004; NSW Government, 2011b). Midlayer and groundlayer components resemble the

Fig. 4 A cool-climate grassy woodland dominated by snow gum (*Eucalyptus pauciflora*) at Rows Lagoon, NSW. Photo: R. Rehwinkel.

adjacent grassland communities, with shrubs locally more common than in the grasslands, and with additional shrub species in Myrtaceae, Fabaceae, Proteaceae, Ericaceae, and Asteraceae (Armstrong et al. 2013).

Box-gum grassy woodlands also occur in the Victorian Midlands bioregion of Victoria (Australian Government, 2006), while woodlands dominated by cold-adapted species, particularly *E. viminalis* and associated species, are also widespread in cooler parts of Victoria and in Tasmania (Australian Government, 2009a,b, 2019). In each state, co-occurring tree, shrub, and forb components vary according to the flora of each bioregion, though many species occur throughout the SE, while others turn over in north-south or east-west gradients (Cosgrove, 2014; Eddy et al., 1998; Falconer, 2004; Kirkpatrick, 1988; Lunt et al., 1998; Marriott and Marriott, 1998; Sharp et al., 2015a; Walker et al., 2001).

Minor Systems

Ephemeral wetlands, bogs, and fens

Areas occupied by shallow waterbodies during wet periods in highland SE NSW transform into grasslands during extended dry spells (Armstrong et al., 2013). The largest of these, Lake George and Lake Bathurst, are, when dry, occupied by a grassland-forbland dominated by species restricted to this community (Armstrong et al., 2013). Smaller ephemeral wetlands on the Monaro basalt plains behave like the larger wetlands to their north (Armstrong et al., 2013; Benson and Jacobs, 1994). A set of grassy ecosystems known as bogs and fens occur at higher elevations bordering the montane regions of the Australian Alpine bioregion and along the Great Eastern Escarpment; these are typified by mosaics of grasses, sedges, rushes and forbs, often with emergent trees and shrubs, and in some high-altitude sites, sphagnum (*Sphagnum cristatum*) (Armstrong et al., 2013; Australian Government, 2009c; Thomas et al., 2000).

Adjoining Grassy Ecosystems

Semi-arid grasslands and woodlands

To the west and north of the above-listed grasslands and grassy woodlands in NSW and Victoria, in semi-arid climates and on flatter landscapes, occur several grassland and grassy woodland formations and vegetation classes that are similar to the those in the SE; however, these generally have different dominants, including more arid-adapted grasses, shrubs, especially those in Chenopodiaceae, and *Eucalyptus* spp. Forbs also differ, with many being annual, rather than the perennials characteristic of the SE (Keith, 2004). Some woodlands in these regions are dominated by *Acacia* spp. (Keith, 2004).

Montane and alpine grasslands, shrublands and woodlands

NSW, Victorian and Tasmanian lowland grassy communities give way to distinctive communities in the montane and alpine regions at the highest elevations. Some of these communities are characterized by grassy groundlayers, others are shrubby; in most of the

montane communities and all of the alpine communities, the grass, forb, shrub and tree components are distinctive, relative to lowland communities (Keith, 2004).

Tableland dry forest communities

On the tablelands and slopes, grassy woodlands give way to a variety of dry open forest communities, mostly occupying steeper terrain with shallow soils (Keith, 2004). These communities are dominated by *Eucalyptus* spp., with *Acacia* and *Allocasuarina* spp. and black cypress-pine (*Callitris endlicheri*) common, and have a greater variety and density of shrubs in Myrtaceae, Asteraceae, Fabaceae and Proteaceae (Armstrong et al., 2013). Where present, the grassy groundlayers may resemble those of the adjacent grassy woodlands occurring on gentler terrain, though some are dominated by the shade-loving weeping grass (*Microlaena stipoides*) or robust tussocks of red-anthered wallaby-grass (*Rytidosperma pallidum*) and spiny-headed mat-rush (*Lomandra longifolia*) (Armstrong et al., 2013).

Adjoining Non-Grassy Ecosystems

In higher rainfall areas or sheltered parts of the ranges and coastal plains, dry forests give way to increasingly wetter eucalypt forests, with shrubby midlayers, some with ferny groundlayers, and soft tree-fern (*Dicksonia antarctica*) and burrawang (*Macrozamia communis*) as occasional midlayer dominants (Keith, 2004; Armstrong et al., 2013). The wettest, most sheltered areas support rainforest types, with distinctive floras and largely lacking *Eucalyptus* spp. (Keith, 2004). Wet forests generally lack grass-dominated groundlayers, though *Microlaena stipoides* may be common.

Secondary Grasslands

Clearing of trees and shrubs from any woody vegetation community, with the retention of a native grassy groundlayer, results in so-called secondary or derived grassland (Australian Government, 2006, 2016; Benson, 1996; Rehwinkel, 2015). Where grassy woodland and dry forest communities are cleared, grasslands resembling the natural communities result, with *T. triandra*, *Austrostipa* spp. and *Rytidosperma* spp. dominating. Where wet forest communities are cleared, novel grassland communities may result, dominated either by *M. stipoides* or *P. labillardierei*, species that prefer higher-nutrient soils resulting from addition of fertilizers for pasture management (Langford et al., 2004).

Ecological Conditions Determining Grassy Ecosystems

Kirkpatrick (1988), Kirkpatrick et al. (1995), and Rehwinkel (1997) reviewed conditions determining SE Australian grasslands, with the following contributing, either alone or interactively:

1. deep, mineral, fertile soils;
2. seasonal drought excluding trees and shrubs;
3. competitive exclusion of woody vegetation by grass roots and sward;
4. attraction by grazing animals to grassland, destroying seedlings of woody plants;
5. severe frosts, particularly low-probability, low-temperature events;
6. wildfires, particularly in combination with grazing;
7. periodic waterlogging, particularly in low-lying sites and in combination with frosts;
8. basaltic or alluvial soils, regardless of climatic conditions;
9. heavy clay soils that crack in summer, causing death of newly established tree seedlings;
10. pre-European settlement burning patterns of the Aboriginal peoples (firestick farming); and
11. previous climates, particularly the colder and drier climates of the Holocene glacials.

Major grassland areas in SE Australia are mapped in Williams and Morgan (2015).

Similar conditions to those that determine presence of grasslands, though generally less severe, determine presence of woodlands (Howling, 1996; Rehwinkel, 1997). Lowland woodlands occur on flat to undulating terrain and fine-textured soils of moderate fertility, with rainfall between 500 and 900 mm p/a, or in rainshadow valleys on the coast receiving rainfall between 700 and 1000 mm p/a (Keith, 2004). The various grassy woodland formations and communities occur on landscapes with varying combinations of the above set of influences (e.g., Keith, 2004; Armstrong et al., 2013).

Fauna of Grassy Ecosystems

The fauna of grassy ecosystems generally shows affinities to fauna across the Australian continent, though there are some species-level differences. Amongst the most iconic of the Australian fauna, the macropods (kangaroos and wallabies, Macropodidae) are represented by the eastern gray kangaroo (*Macropus giganteus*), a large, gregarious grazer of grasslands, open woodlands and dry forests. It is one of the largest kangaroos and adapted to survive on poor quality grasses in open country in

SE Australia (Hume et al., 1989). The Tasmanian Midlands are that state's strongholds for *M. giganteus* (Australian Government, 2009a). Other, smaller macropods and macropod allies (Potoroidae) occur in grassy ecosystems, including the eastern bettong (*Bettongia gaimardi*), which was extirpated in SE mainland grasslands soon after European colonization (Costin, 1954), but survives in Tasmania, where it too has its stronghold (Australian Government, 2009a). In Victoria, the eastern barred bandicoot (*Parameles gunnii*) is confined to one grassland site (Wynyard, 2014), though it remains common in Tasmania ("Eastern Barred Bandicoot" website).

Other marsupials found in grassy ecosystems include, very sparingly in woodlands in NSW, the koala (*Phascolarctos cinereus*) (NSW Government, 2011c) and squirrel glider (*Petaurus norfolcensis*) (Australian Government, 2006), very commonly throughout the SE, the common wombat (*Vombatus ursinus*) (Australian Government, 2009a, 2016), and the three carnivorous marsupials, Tasmanian devil (*Sarcophilus harrisii*), eastern quoll (*Dasyurus viverrinus*) and spotted-tailed quoll (*Dasyurus maculatus*), common now only in Tasmania (Australian Government, 2009a). One of the three surviving monotremes, the short-beaked echidna (*Tachyglossus aculeatus*) remains common in grassy woodlands throughout the SE, as do a number of bats (order Chiroptera). Less common are native rodents (Muridae).

Avifauna of grassy ecosystems include emu (*Dromaius novaehollandiae*), which is now locally rare in the SE mainland, and Australian bustard (*Ardeotis australis*), which has been extirpated there (Menkhorst et al., 2017). The most distinctive grassy ecosystem birds are cockatoos (Cacatuidae) and parrots (Psittacidae), specifically those in the genera *Cacatua*, *Eolophus*, *Platycercus*, *Polytelis*, *Psephotus*, and *Neophema*, which feed principally on seeds of grasses, and *Eucalyptus* and *Acacia* spp. in dry forests, woodlands and grasslands (Menkhorst et al., 2017). Other distinctively SE Australian grassy ecosystem birds include magpie-lark (*Grallina cyanoleuca*), Australian robins (Petroicidae), thornbills, gerygones and weebill (Acanthizidae), whistlers and shrike-thrushes (Pachycephalidae), pardalotes (Pardalotidae, Fig. 5), some honeyeaters (Meliphagidae) and most of the woodswallows, butcherbirds and Australian magpies (Artamidae) (Menkhorst et al., 2017). Grassy ecosystem birds of distinctly non-Australian bird families, i.e., those with a greater distribution outside Australia, include many hawks (Accipitridae), falcons (Falconidae), two quails (Phasianidae), a lark (Alaudidae), a pipit (Motacillidae) and several corvids (*Corvus* spp. in Corvidae) (Menkhorst et al., 2017).

Reptiles include several threatened species that are all but confined to grassy ecosystems in SE Australia, including grassland earless dragon (*Tympanocryptis lineata*), striped legless lizard (*Delma impar*), pink-tailed worm-lizard (*Aprasia parapulchella*) and little whip snake (*Suta flagellum*) (Australian Government, 2016). Other herpetofauna common in lowland grasslands include eastern common froglet (*Crinia signifera*), spotted marsh frog (*Limnodynastes tasmaniensis*), eastern brown snake (*Pseudonaja textilis*), eastern blue-tongued skink (*Tiliqua scincoides*), shingleback (*T. rugosa*, Fig. 6) and Cunningham's skink (*Egernia cunninghami*).

Some invertebrates are closely tied to grassy habitats. On the SE mainland, golden sun moth (*Synemon plana*), Canberra raspy cricket (*Cooraboorama canberrae*) and perunga grasshopper (*Perunga ochracea*), are three threatened grassland specialists, while the rare Key's matchstick grasshopper (*Keyacris scurra*) is tied to species of family Asteraceae in grassy woodlands (Australian Government, 2016). Grassland-insect relationships are similarly close in Tasmania, where a skipper butterfly (*Anisynta dominula*) and Ptunnarra brown butterfly (*Oreixenica ptunnarra*) both feed on *Poa* spp., and the Tunbridge looper moth (*Chrysolarentia decisaria*) is restricted to one grassland site (Australian Government, 2009a).

Human Interactions: Indigenous Connections and European Exploitation

Indigenous Land-Uses: Pre1788

The interactions of Aboriginal peoples with SE Australian grassy ecosystems were given scant recognition in early 20th century literature (e.g., Costin, 1954). Writing of the Monaro region of SE Australia, Hancock (1972) said it was thought that Indigenous

Fig. 5 Striated pardalote (*Pardalotus striatus*), a grassy woodland belonging to a typical Australian family. Photo: R. Rehwinkel.

Fig. 6 Shingleback (*Tiliqua rugosa*), a common grassy woodland reptile, NSW. Photo: R. Rehwinkel.

peoples only arrived there some 15,000 b.p., and, while focussing on their hunting practices, particularly the harvesting of Bogong moths (*Agrotis infusa*), Hancock acknowledged that some observers thought that grasslands and open woodlands did not merely result from prevailing climate-soil conditions and plant-animal interactions, but some may indeed be partly anthropogenic, resulting from Aboriginals' firesticks.

In recent years, an increasing body of literature emerged, putting the Indigenous inhabitants of Australia firmly in the picture. It is now generally recognized that Aboriginals had a longer tenure of the continent, by as much as 50,000 years b.p. (Gott et al., 2015). Chief amongst those who have written about Aboriginal land-uses, Gammage (2011) argued that Aboriginals shaped Australian grassland and woodland systems in a highly complex manner by careful land-management techniques, including use of firestick farming. Gott et al. (2015) and Pascoe (2018) present evidence of sophisticated agricultural practices of the Aboriginal cultures in grassy ecosystems, citing instances of cultivation of root crops, including, amongst others, the murrnong (*Microseris lanceolata*, Fig. 7), a grassy ecosystem forb that was once super-abundant and widespread throughout the SE mainland, but is now rare. Pascoe (2018) also cites instances of large-scale harvesting and storage of grain crops from native grasses and even irrigation and sowing of grain crops, though Gott et al. (2015) suggests that this occurred mainly in arid regions, rather than in the south-east. Aboriginals established permanent or semi-permanent settlements in some temperate grassland areas (Gott et al., 2015; Pascoe, 2018).

Early European Land-Uses: 1788 to 1950s

European colonization started with establishment of the Sydney penal settlement in 1788. It was not until the early 19th century that country west of Sydney, occupied by extensive grasslands and grassy woodlands, attracted the European explorers, who were

Fig. 7 Murrnong (*Microseris lanceolata*), an important staple of pre-European cultures. Photo: R. Rehwinkel.

Fig. 8 Grassy woodland transformed into productive croplands, at the expense of the ground flora, South-western slopes, NSW. Photo: R. Rehwinkel.

followed by colonists and their stock. It is often said, referring to Australia's agricultural wealth, that "Australia rode on the sheep's back" (Gott et al., 2015), but it is rarely acknowledged that wealth generated from wool resulted because the sheep grazed exclusively on native grasses and forbs. The grasslands in the SE were progressively opened up by colonists (Fig. 8): in NSW, firstly in the Bathurst region by 1813 (Keith, 2004), then the Goulburn to Canberra region by 1823, the Monaro by 1824, the Tasmanian Midlands by 1825, and Victoria, starting in 1835 (Gott et al., 2015).

The early phases of agriculture in SE Australia were marked by rapid growth of flocks of sheep and herds of cattle, which led to, or co-occurred with:

1. overgrazing of native grasslands;
2. the beginnings of substantial soil erosion;
3. massive stock losses due to droughts;
4. European rabbit (*Oryctolagus cuniculus*) plagues that followed their introduction and expansion of their populations;
5. "ring-barking" to expand pastures by deliberate destruction by cutting of the cambium layer of trees; and
6. declines of some productive native grasses to be replaced by exotic annual species (Costin, 1954; Benson, 1994; Gott et al., 2015).

SE Australian grassy ecosystems now contain a significant number of introduced plant and animal species, resulting from either deliberate or accidental introductions. The misguided introduction of European red fox (*Vulpes vulpes*) was to introduce the British sport of fox-hunting to Australia ("Fox Scan" website), and other species, such as European starling (*Sturnus vulgaris*) were introduced to control crop pests ("PestSmart" website). Other species were introduced deliberately for their role as important pasture plants; examples include the European grasses cocksfoot (*Dactylis glomerata*), phalaris (*Phalaris aquatica*), fescues (*Festuca* spp.), rye-grasses (*Lolium* spp.) and clovers (*Trifolium* spp.). Though now important economically, they are considered invasive in SE Australian grasslands. Other species, including the European St John's wort (*Hypericum perforatum*), serrated tussock (*Nassella trichotoma*) and Chilean needle-grass (*N. neesiana*) from South America, and African lovegrass (*Eragrostis curvula*), now considered to be amongst the most intractable of invaders in grasslands and woodlands, were accidental introductions (Armstrong et al., 2013; Australian Government, 2016; Eddy et al., 1998).

Agricultural and Infrastructure Development Post-World War II

Historical adverse changes to grassy ecosystems were likely the result of widespread misunderstanding of Australian conditions (soils, climates, plant responses), though there had been early warnings of caution (Costin, 1954; Benson, 1994; Gott et al., 2015). The early transformations were intensified with the advent of modern technologies from the time of World War II: increasing use of motorized farm equipment and state-sponsored schemes, including increased tree-clearing, introduction of exotic pasture

species and subsidized chemical fertilizer use, though irrigation was generally limited in the SE (Costin, 1954; Hancock, 1972; Benson, 1994; Gott et al., 2015). Towards the end of the 20th century and after, establishment of commercial non-native pine plantations and other forms of intensive agriculture (olives, vineyards) impacted on native grassy ecosystems (Australian Government, 2016).

Alongside agricultural impacts on natural ecosystems were increases in urban populations, resulting in increased infrastructure development in the form of widening of highways, pipeline developments and urban intensification, including rapid increases in urban, suburban and rural residential development, all of which impacted on grasslands and grassy woodlands (Australian Government, 2016; Fallding, 2002; Friends of Grasslands, 1998; Gott et al., 2015). Anthropogenic climate change is also recognized as a threat to grassy ecosystems (Australian Government, 2009a, 2016). Estimates of the extent remaining of some grassy ecosystems communities are provided in the following examples:

- of the box-gum grassy woodlands in SE NSW, <4% are estimated to remain (Thomas et al., 2000); and
- of the approximately 890,000 ha of natural grassland that existed in SE Australia pre-European settlement, now only 34,000 ha are estimated to remain, which is a 96.2% decline (Australian Government, 2016; Williams and Morgan, 2015).

Recognition of the decline of the extent and condition of grasslands and grassy woodlands, and an emerging interest in conservation or sustainable use of these systems in SE Australia, coincided with the introduction of the first state-level vegetation protection regulations in the early 1990s (NSW Government, 1997), which was followed by introduction of Australian Government legislation to recognize many grassy communities as endangered (Australian Government, 2006, 2008, 2009a,b,c, 2016; NSW Government, 2005a, 2011a,b). State and Commonwealth funds were made available to initiate research and conservation activities and non-government agencies and state and territory governments increased efforts in conservation actions, including establishment of formal nature reserves, off-reserve conservation measures and community engagement programs. Community groups and non-government agencies assist in many aspects of this conservation effort. Sustainable agricultural use of native grasslands has also emerged.

Human Interactions: Greater Understanding, Targeted Conservation, Research, Community Engagement, and Sustainable Land-Use

Due to the volume of actions undertaken over the last three decades in SE Australia, and the necessity for brevity, the following sections focus on actions undertaken in SE NSW and the ACT, with references to Victoria and Tasmania to illustrate specific points, where necessary.

Research

Classification and mapping

Grassland and woodland communities were subjected to ever-more refined classifications in SE NSW, beginning with Costin (1954), and proceeding with Benson (1994), Thomas et al. (2000), and finally Armstrong et al. (2013), and in the ACT, by Pryor (1938), Ingwersen et al. (1974), Sharp (1997), and Bains et al. (2013). Grasslands were classified throughout SE Australia by Kirkpatrick et al. (1995). Kirkpatrick et al. (1995) defined 28 communities ranging from South Australia through Victoria, NSW and Tasmania. Following the rationale and methodologies as in Thomas et al. (2000), which focussed on forest ecosystems in NSW for the Comprehensive Regional Agreements, a Victorian study (Victorian Government, 1996) led to the comprehensive mapping of all vegetation communities there, including grasslands and grassy woodlands ("Bioregions and EVC benchmarks" website). Tasmania also has a comprehensive vegetation classification (Kitchener and Harris, 2013).

In a project including the ACT and surrounding Southern Tablelands region of NSW, Fallding (2002) presented pre-European and contemporary mapping, and a broad-scale review of ecosystems focussing on grasslands and grassy woodlands. Remote-sensing modeling was undertaken for grassy ecosystems covering SE NSW and the ACT (ERIC, 2001; Rehwinkel, 2005; Walter and Schelling, 2004, 2005). Region-wide vegetation surveys were undertaken for the NSW South-western Slopes bioregion followed by classification, mapping and remote-sensing modeling of grassy ecosystems there (Benson 2008; Priday 2005; Rehwinkel and Priday, 2003; Rehwinkel, 1998). Keith (2004) maps all NSW vegetation formations.

Research on ecology, genetics, management and restoration

Early grassland research focussing purely on conservation management, rather than economic use, was pioneered in Victoria (Stuwe, 1986) and Tasmania (Kirkpatrick, 1993), and later, with a broadening focus throughout the south-east (Craigie and Hocking, 1998; Kirkpatrick et al., 1995).

Research was carried out in the ACT, initially as a result of conflicts between development and conservation of grasslands, to assess potential sites for conservation, undertake flora and fauna surveys, and ultimately, once reserves had been established, on the ecology and genetics of threatened grassland reptiles, invertebrates and plants, followed by fine-scale assessments, mapping of sites and management trials (Friends of Grasslands, 1998; ACT Government, 2005, 2015). The ACT Government commenced long-term monitoring of grassland sites in 1993; this is proposed to continue until 2112 (Sharp and Dunford, 1996).

In SE NSW, similarly reacting to conflicts between the development industry and conservation interests, more limited grassland research was undertaken (Fallding, 2002), with the exception of more extensive site-surveys covering SE NSW region for the Grassy Ecosystems Database (GEDB) (Rehwinkel, 1997; “NSW BioNet” website), which resulted in development of remote-sensing modeling of grasslands and grassy woodlands and a regional grassland community classification (Armstrong et al., 2013). Research in grassy woodlands, principally in the NSW South-western Slopes bioregion focussed on understanding aspects of woodland functioning and management (Lindenmayer et al., 2010; McIntyre et al., 2014; Michael et al., 2018; Prober and Thiele, 1995, 2004; Prober et al., 2002, 2004a,b; Prober, 1996). Woodland research undertaken in SE Queensland is accepted as being applicable to grassy ecosystems in SE Australia (McIntyre et al., 2002).

Research on the genetics of grassy ecosystem flora species (e.g., Prober and Thiele, 1993; Young, et al., 2000; Broadhurst et al., 2012, 2015) focussed on threatened species and others with potential for rehabilitation or restoration of grassy communities. Research into taxonomy of a grassland reptile has yielded answers to questions that are important for conservation of threatened species: the formerly considered single taxon, *Tympanocryptis pinguicollis*, has been split into four taxa: *T. pinguicollis* from Victoria, *T. lineata* from the Canberra region, *T. osbornei* sp. nov. from the Monaro and *T. mccartneyi* sp. nov. from Bathurst (Melville et al., 2019). This work postulated that the Victorian species may be the first Australian mainland reptile species to become extinct, and also highlights the critical conservation status of the other three taxa, with particularly the Bathurst species, known from only two specimens.

Research on the ecology and functioning of grasslands has been undertaken to understand management (Antos and Williams, 2015; Morgan and Williams, 2015; Morgan, 2015; Reid, 2015; Robinson, 2015; Sharp et al., 2015b; Williams and Morgan, 2015). Management trials have been undertaken in grassland and woodland nature reserves by NSW National Parks Service, though these tend not to be well-documented. Research focus on connectivity has developed planning and spatial modeling, in some cases undertaken specifically for grassy ecosystems, and at ever-decreasing scales, from the national scale (e.g., Doerr et al., 2013) to the regional (Barrett and Love, 2012; Love et al., 2014a,b).

Formal Conservation

Early efforts: National parks pre-1990

Few lowland grasslands and woodlands were conserved in formal conservation reserves in SE Australia, although montane and alpine systems, including bogs, fens, montane woodlands and grasslands and the Tasmanian buttongrass moors were protected in parks such as Kosciuszko in NSW (NSW Government, 2014), the Greater Alpine National Parks in Victoria (Victorian Government, 2016), and in the Tasmanian Wilderness World Heritage Area (Tasmanian Government, 2016). In the ACT, Namadgi National Park and some of the reserves surrounding Canberra protected areas of grassland and woodland that are now recognized as endangered communities (ACT Government, 1999, 2010; Armstrong et al., 2013; Bains et al., 2013).

Recent efforts: National parks and nature reserves post-1990

On the mainland, the ACT Government was an early adopter of the need to target the conservation of lowland grassy communities, with the gazettal of the first set of nature reserves specifically for grasslands in the mid-1990s as a result of studies that identified rare fauna, flora and communities that were potentially to be impacted on by development of suburbs in the Gungahlin district, and other reserves were subsequently gazetted elsewhere (ACT Government, 2005, 2015).

Conservation of grassy ecosystems in the ACT culminated in the establishment of Mulligans Flat Sanctuary, a collaboration between ACT Government, two non-government agencies, and researchers at Australian and international institutions, with the aims not only to conserve grassy woodland, but also to undertake intensive research and woodland restoration programs, and reintroduce woodland fauna species that have become regionally extinct within predator-proof fencing (ACT Government, 2016; McIntyre et al., 2014).

Specifically targeted woodland conservation in NSW was initiated by the Regional Forest Agreement (RFA) process (NSW Government, 2001), which comprehensively identified under-represented vegetation communities; several grassy woodland reserves were established resulting from this and subsequent similar processes (NSW Government, 2006). The RFA processes, however, failed to identify grasslands, and in NSW, the first set of reserves specifically gazetted to conserve lowland grasslands in SE NSW were identified through specific project work or through planning processes as a result of conflicts with infrastructure development (Fallding, 2002; NSW Government, 1999, 2007, 2009a; Rehwinkel, 1996a, 2003a). Kuma NR was amongst the first large areas set aside as to offset loss of a smaller area following development pressures.

Formal grassland conservation reserves are also established in Victoria (Victorian Government, 1998), though a promised 15,000 ha offset reserve is still awaiting formal protection (“The Age” website). Lowland grasslands remain poorly reserved in the formal Tasmanian reserve network (Australian Government, 2009a; “Township Lagoon” website).

Despite the above efforts, of the natural grassland in pre-European highlands NSW, only 600 ha, or 0.1% of the former extent are formally conserved (Australian Government, 2016). In the ACT, an estimated 2200 ha of native grassland are protected within the formal reserve network or are otherwise managed for conservation (Australian Government, 2016), which is proportionately greater relative to its pre-settlement extent than that of the other three states.

Conservation Planning

Developing strategies for planning, acquiring and managing grassland and grassy woodland reserves, and also to set priorities for off-reserve conservation and sustainable multi-use of sites, generally falls either to the Australian or state or territory governments, often in partnership with each other, and usually in concert with non-government agencies, community groups and the wider community. Examples of plans and strategies include region-wide plans for biodiversity or general ecosystems (Fallding, 2002; Murray CMA and OEH, 2012), or the plans focussing on specific grassy ecosystems, including ACT woodland and grassland strategies, national recovery plans for natural temperate grassland and box-gum woodland, and species-related recovery or action plans (ACT Government, 2005, 2015; Australian Government, 2006, 2008; “ACT Action Plans” website; “EPBC Recovery Plans” website).

ACT operates an on-line mapping tool that enables infrastructure planning for significant vegetation types and species, including grassy ecosystems and a suite of associated threatened flora and fauna, amongst other assets (“ACT Mapi” website). Fine-scale plans have been developed for each threatened grassy ecosystem species in NSW; these are accompanied by defined projects and funding for projects is available (“Saving Our Species program” website).

At the landscape-scale, Local Lands Services (LLSs) have developed catchment management plans for natural resources in their areas of concern; these have invariably marked grasslands and grassy woodlands for attention because of their threatened status, and as such, LLSs have prioritized actions and directed funding to landholders and community groups for off-reserve conservation (“South East Local Land Services” website). South East LLS was responsible for developing connectivity plans for the region (Love et al., 2014a) and have contributed in the recovery planning processes (Australian Government, 2008). The LLSs occur throughout NSW, and equivalent agencies occur throughout Victoria and Tasmania.

In NSW, the LLSs have other responsibilities relating to conservation of grassy ecosystems, including management responsibility for the system of traveling stock reserves (TSRs), which are parcels of land set aside by legislation in the early 1900s to ensure herds of cattle and sheep could be walked across the landscape for drought relief or to markets (Phillips, 2000). Because these reserves generally had limited grazing and little if any pasture modification since their establishment, they retain excellent examples of endangered grassy ecosystems and many have populations of threatened flora and fauna (Australian Government, 2006, 2008; O’Loughlin et al., 2017; Rehwinkel, 1996a). The LLSs have worked with ecologists from NSW State Government and community organizations since the mid-1990s to refine management planning and mapping of TSRs (“Australian Government TSR” website; “South East Local Land Services” website; “TSR map” website).

Other roles of LLSs that assist landholders in conservation of grassy ecosystems include farm planning, capacity building via workshops, field days and landholder engagement, administering and servicing native vegetation legislation, and providing advice on pest animal and invasive plant control (“South East Local Land Services” website).

Off-Reserve Conservation

Covenants and stewardships

The NSW Government initiated a system that applies in-perpetuity conservation agreements to private land sites, a number of which have areas of significant grasslands or woodlands. While remaining in private ownership, these sites fall under the responsibility of the NSW Biodiversity Conservation Trust (BCT) (“NSW Biodiversity Conservation Trust” website), which monitors the agreements and provides management assistance to the site’s owners. BCT operates a revolving fund that enables purchase and subsequent sale to conservation managers and some significant grassy ecosystem sites have been protected (e.g., “Bunhybee Grasslands” website). A similar revolving fund occurs in Victoria, where over 3000 ha of grassland are conserved (Williams and Morgan, 2015; “Trust for Nature” website).

The Australian Government introduced the Environmental Stewardship Program to provide support for landholders with box-gum woodlands throughout SE Australia. This program employed a competitive tendering process, delivering funded contracts to landholders to assist management of sites (Burns et al., 2016). Some landholders subsequently entered in-perpetuity agreements with the NSW Government and in 2018, the NSW Biodiversity Trust introduced a stewardship fund specifically for grasslands in the NSW Monaro region (“NSW Biodiversity Conservation Trust” website).

Informal reserves on state-owned and private lands

In addition to the NSW National Parks and Wildlife Service, which manages the formal reserve network in NSW (NSW Government, 1999, 2014), other NSW Government agencies play a part in conserving native grassy sites (Friends of Grasslands, 2000). NSW Department of Lands work alongside community groups, developing Crown land (State-owned public land) reserves with the aims of environmental protection and passive recreation (see Fig. 9), or additionally, to maintain common grazing at some town commons (Brooks Hill Reserve Trust, 1997; Rehwinkel and Treweek, 2012; Sharp, 2012). Several public land sites in NSW with grassland or woodland values await conservation action (“Greening Australia” website) with some identified as priority sites for threatened species projects subject to funded works (“Saving Our Species program” website).

Paralleling actions undertaken by state agencies in NSW and ACT are efforts undertaken solely by landholders, community groups and local government and non-government agencies, either to establish informal grassland and woodland reserves on lands of various tenures, or to assist government agencies in a voluntary capacity, including on government-owned and private lands in SE NSW and the ACT (Kosciuszko to Coast, 2013a; Robertson and Parker, 2018; “Friends of Grasslands” website). Bush Heritage

Fig. 9 Awaiting effective conservation action: a floristically diverse grassland on a Crown land reserve at Bibbenluke, NSW. Photo: R. Rehwinkel.

Australia manages a reserve with significant areas of grassland and woodland (*"Scottsdale Reserve" website*), and a private land site is being developed as a reserve with a predator-proof fence (*"Wandiyali Restoration Trust" facebook site*).

Informal private land conservation, where there is no formal protection afforded by an agreement between a federal, state, territory or non-government agency and the landholder, has been initiated by private individuals, with or without funding assistance. Private individuals conserving patches of grassland or grassy woodland largely remain undocumented ([Rehwinkel, 1996b,c, 2001](#)). I have visited sites where landholders have fenced areas containing grassy ecosystem remnants, some of which exceed 30 ha, which is larger than some formal grassland reserves managed by state agencies ([NSW Government, 2009a,b](#)). Some sites were established as early as the 1960s, predating the period when grassland conservation had become a part of the priorities and policies of state and territory governments. Areas were fenced for protection from grazing, and some receive management in the form of control of invasive plants and feral animals.

While private and local government land sites contain valuable remnants of grassy vegetation, their long-term security is not assured, unless owners or managers enter into formal protection agreements, without which, such remnants are vulnerable to loss or degradation, due to factors that would mostly include changing economic pressures. For example, the fences around remnants fall into disrepair, the owners are forced to graze sites more heavily, or there may be increased invasive plant or feral animal pressures that managers cannot afford to control.

Examples exist of grassland reserves that are owned and managed by a local government in Tasmania ([Jerry deGryse Pty Ltd., 1990](#)) or a non-profit, non-government agency in Victoria (*"Graigieburn grasslands" website*).

Conservation on traveling stock reserves and country cemeteries

NSW government agency ecologists, along with a number of non-government and community groups, including World Wide Fund for Nature, managers and associates of conservation management networks and Friends of Grasslands ([Eddy, 2007](#); [Rehwinkel, 1996a, 1998, 2003b](#); *"South East Local Land Services" website*, *"Friends of Grasslands" website*), undertook conservation assessments of traveling stock reserves (TSRs) in the south-east of the state, beginning in 1995 and continuing through to the time of writing. Data from assessments (the 'Grassy Ecosystems Database' (GEDB)), together with those from surveys undertaken by other workers beyond the SE, are collated in NSW and Australian Government databases (*"ALA" website*; *"Australian Government TSR" website*; *"NSW BioNet" website*). Project-workers consulting with TSR management bodies and other government and non-government groups with interests in conservation of TSRs sought to ensure that TSRs with identified high conservation values are managed to retain those values ([Eddy, 2002](#); [Rehwinkel, 1996a](#)). The TSR managers have, as a result, recognized the special values of the TSRs (*"TSR map" website*). At many TSRs, their managers have responded with application of increasingly sympathetic conservation management, often having sourced funding, and in some cases, erecting interpretive signage outlining the sites' values.

Many cemeteries in regional towns have retained high conservation values because of the benign neglect that they have received ([Jones, 1998](#); [Rehwinkel, 1996a](#)). The surrounding rabbit-proof fencing of most cemeteries, lack of stock grazing, the occasional

slashing or mowing applied over parts of the sites to enable access, and often, lack of any treatment to some areas of grassy vegetation beyond the aprons of gravesites have contributed to retention of values. Conservation gains have been made in collaboration with government and non-government groups, with conservation management actions applied to a number of sites in SE NSW and the ACT, including erection of interpretive signs to outline values of sites, application of defined mowing regimes and invasive plant control ("Friends of Grasslands" website; "Hall cemetery" website; "Sydney Morning Herald" website).

Education and Community Engagement

Recovery planning and other formal programs

Many Australian, state, territory and local government departments, non-government agencies and community groups have played significant roles in communicating with each other and the broader community, disseminating information on conservation of endangered grassy ecosystems and their component threatened species in SE Australia; I describe these here under the broad fields of education and community engagement (Fig. 10). NSW and ACT government ecologists have played roles in public consultation, education and community engagement, with sections in the departments now devoted to that aspect of conservation, focussing on providing technical assistance and support for actions on private lands and promoting voluntarism (Rehwinkel, 2003d; "ACT volunteering" website, "Saving Our Species program" website). Community engagement in Victoria is reviewed in Williams (2015) and Reid (2015).

Recovery planning for threatened flora, fauna and endangered ecological communities has guided voluntary activities. Recovery planning depends on collaborative approaches, invariably relying on land-managers with responsibilities for conservation assets on various tenures. If from public agencies, land-managers frequently rely on community groups to assist in conservation efforts. Land-managers or community groups acting on behalf of landholders rely on funding sources that include the Australian, state, territory and local governments, and less commonly, from philanthropic organizations. Community organizations that assist in these activities include Catchment Management Groups, Friends of Grasslands, Greening Australia, and Landcare and ParkCare groups ("ACT Landcare" website; "ACT volunteering" website; "Friends of Grasslands" website; "Ginninderra Catchment Group" website; "Greening Australia" website; "Molonglo Conservation" website). In NSW and the ACT, community-facilitated management and restoration works have been undertaken for a number of threatened flora and fauna species ("ACT Action Plans" website; "EPBC Recovery Plans" website; "Saving Our Species program" website).

In efforts to ensure that information on threatened flora, fauna and endangered ecological communities, the Australian, state and territory governments developed online profiles for each threatened entity, which include amongst them many from grassy ecosystems ("ACT Government threatened species and ecological communities" website; "Australian Government species profile and threats database" website; "NSW threatened species profile search" website; "State wide integrated flora and fauna teams" website; "Tasmanian Government threatened species link" website). In some cases, profiles rely on information sourced through engagement with community members, industry consultants and researchers.

In NSW, threatened species profiles were further developed to provide a link from each threatened entity's profile to a program that has developed species- or threatened ecological community-specific project-planning; this program enables individuals or community groups to select a project for a species or threatened ecological community, and to source specifically targeted funding to complete tasks on one or more of a set of identified sites for each species or community (NSW Government, 2016, 2017; "Saving Our Species program" website).

Fig. 10 Community engagement in NSW. Photo: R. Rehwinkel.

Flora and management guides

Inter-agency government and community collaboration in community engagement to assist grassland managers in NSW and the ACT resulted in the publication of a grassland flora field guide (Eddy et al., 1998), enabling farmers, land-managers and interested members of the public to identify grassland flora species in SE Australia. A number of other field guides have been developed in NSW, ACT, Victoria and Tasmania (Cosgrove, 2014; Falconer, 2004; Kirkpatrick, 1988; Lunt et al., 1998; Marriott and Marriott, 1998; Sharp et al., 2015a; Walker et al., 2001; "Field guide to plants of the Molonglo Valley" website).

Inter-agency and community collaboration was instrumental in the development of material to guide management and to assist conservation efforts of landholders and managers of grassy ecosystem sites (Eddy, 2002; Grassy Box Woodland CMN et al., 2011; Rawlings et al., 2010; Rehwinkel, 2013; Ross, 1999; Sharp et al., 2005; Stol and Prober, 2015), or to guide in the assessment of sites for their values and monitoring of the outcomes of management actions (Sharp and Gould, 2014; Rehwinkel, 2015).

Conservation management networks

The establishment of conservation management networks (CMNs) was a community engagement effort to assist with conservation of grassy ecosystems (Eddy, 2007; Lunt et al., 2010; McLeish et al., 2013; Rehwinkel, 2003b; Rehwinkel, 2003c,d; "Far South Coast CMN" website). A CMN is a network of remnants of native vegetation, their owners or managers and other interested individuals. CMNs usually focus on a single ecosystem type, because the management needs of each are usually relatively uniform. CMNs are managed by coordinators, who assist land managers to learn about the ecosystems, their fauna and flora, and how to manage them according to the goals of either conservation or production. The coordinators' role is to communicate with members of the CMN through newsletters, forums and field days, and to put members in touch with ecologists, botanists and fauna specialists and others with particular management expertise, including other members of the CMN. CMN coordinators also enable sourcing of funding for project work, and perform other supporting roles, including development and maintenance of site databases. CMNs relied on government funding, and unfortunately, when government priorities shifted, funding ceased and three CMNs for grassy ecosystems in NSW dissolved (McLeish et al., 2013). CMNs continue to operate, with one in SE NSW and several in Victoria ("Far South Coast CMN" website; "Victorian CMNs" website), with continuing funding from various sources. The surviving CMNs are now rarely concerned exclusively with grassy ecosystems, for which the original model was devised; rather they have a more tightly restricted regional focus than that of some of the now defunct CMNs.

Connectivity partnerships

Falling under the umbrella of the Great Eastern Ranges Initiative, a continental-scale landscape connectivity partnership, are several SE NSW regional partnerships with grassy ecosystems as amongst their connectivity targets (Pulsford, et al., 2013; "Bush Heritage K2C" website; "Great Eastern Ranges" website; "K2C" website; "Slopes to Summit" website). An unforeseen outcome of the regional partnerships, which include government and non-government groups that previously worked together only minimally, has been greater coordination, less duplication of conservation effort and improved communication to landholders and land managers. The Kosciuszko to Coast partnership undertook a number of grassy ecosystems conservation projects ("K2C" website; Kosciuszko to Coast, 2013a).

Community groups

Locally-based community groups have contributed significantly to grassy ecosystem conservation in SE Australia, and one with an emphasis on education and advocacy is Friends of Grasslands (FOG) ("Friends of Grasslands" website). This group hosts forums, conferences and field trips, and as part of its advocacy roles, submits comments to formal Australian, ACT and NSW government consultation processes. FOG also undertakes monitoring of grassland recovery at a Bush Heritage Australia reserve and undertakes on-ground works at sites in the ACT and NSW ("Friends of Grasslands" website).

A major government-funded program, Landcare, has delivered government funds to communities for works on private and public lands since the 1980s ("ACT Landcare" website; "Landcare Australia" website). While much effort in Landcare's early years was expended on tree-planting, soil erosion works and other on-farm programs, increasingly, efforts have assisted landholders protecting conservation assets, including grassy ecosystem sites, by providing funding for exclusion fencing and other management assistance, including hosting workshops and field days for information dissemination. Land for Wildlife ("Land for Wildlife" website), a voluntary property registration scheme, also receives government funding to assist landholders wishing to conserve grassy ecosystem sites.

Greening Australia provides assistance to landholders and communities ("Greening Australia" website). Receiving funding from donations and Australian, state and territory governments, Greening Australia (GA) draws on the resources of community volunteers (Fig. 11). GA was also initially principally concerned with returning trees to degraded agricultural landscapes but it too is increasingly assisting landholders with sites with grassy ecosystems. Greening Australia's has a role in providing education and training ("Greening Australia" website), and published a bird field guide (Taws, 2007).

In recent decades, GA used its considerable intellectual capital in developing propagation and establishment techniques in the field of grassland and grassy woodland restoration and has applied these widely. Examples include programs throughout the SE and at the Cumberland Plains near Sydney (ACT Government, 1999, 2016; Kosciuszko to Coast, 2013a; NSW Government, 2005b, 2009b; Rehwinkel, 2013; "Greening Australia at Scottsdale" website). In Victoria GA and others have established seed orchards for grassland species and have undertaken extensive experimental trials and successful establishment of restored sites (Gibson-Roy and Delpratt, 2015; Delpratt and Gibson-Roy, 2015).

Fig. 11 Grassy ecosystems restoration often depends on community volunteers. Photo: R. Rehwinkel.

Several other groups are active in grassy ecosystems conservation. Voluntary community groups assist the ACT Government in managing grassy woodland sites ([“Friends of Mt. Majura” website](#); [“Red Hill Regenerators” website](#)). Ginninderra Catchment Group (GCG) is active in grassland restoration trials, using fire to enhance diversity in a volunteer-led, government-funded project ([“Ginninderra Catchment Group” website](#); [“Ginninderra Catchment Group burning trials” website](#)). GCG has produced interpretive materials for engaging with the wider community, including a flora guide ([“Ginninderra Catchment Group flora guide” website](#)) and catchment planning strategies ([Ginninderra Catchment Group; 2000](#)). Molonglo Conservation, similarly, has developed a planning strategy and programs for community engagement, and is undertaking a Saving Our Species project ([“Molonglo Conservation”, website](#)).

Indigenous engagement

Focus in recent years has turned to Indigenous peoples’ interactions with grassy ecosystems. Examples include application of traditional land management techniques and recognition of indigenous values ([Kosciuszko to Coast, 2013a](#); [Kosciuszko to Coast, 2013b](#); [Natural Resources Advisory Council, 2010](#)), promotion of traditional plant use ([ACT Government, 2014](#); [Williams and Sides, 2008](#)), programs undertaken by Greening Australia ([“Greening Australia Indigenous culture” website](#)), and an on-ground project to reintroduce yamfields, using murrnong, (*Microseris lanceolata*), and other species ([“Bundian Way Yamfields” website](#)).

Grassy ecosystems in art and horticulture

Artists have engaged with grassy ecosystems and their managers to bring them to a wider audience; examples are the fine art by James ([“Christine James art” website](#)), line drawings of grassland species by Bedingfield (e.g., [Friends of Grasslands, 1998](#)); woodland photographs in [Lindenmeyer et al. \(2005\)](#) and grassland photography in [Young and McIntyre \(2018\)](#).

Considerable interest in recent years has turned to indigenous grassy ecosystem flora species for use in home gardens and public landscaping ([Fig. 12](#)). This is reflected in development of a grassy ecosystems garden at the Australian National Botanic Gardens, and the Southern Tablelands Ecosystems Park, devoted to locally indigenous plants including grassy ecosystem species, at the National Arboretum, Canberra ([“Australian National Botanic Gardens” website](#); [“National Arboretum Canberra” website](#)). These gardens function as places of engagement with grassy ecosystems flora for residents and tourists that otherwise would not be exposed to grasslands and woodlands in natural settings. Many local nurseries now stock grassy ecosystems plant species.

Towards More Sustainable Land-Use in the Agricultural Landscape

Sustainable land-use

Native grasslands, grassy woodlands and their flora and fauna have become the focus not only for conservation, but in sustainable agriculture ([McIvor, 2005](#); [Barlow and Thorburn, 1999](#); [O’Dwyer and Hamilton, 2003](#); [“Stipa” website](#)). [Massey \(2017\)](#), a grazier from the Monaro grasslands, exemplifies a trend towards ‘regenerative agriculture’ in SE NSW. Research has focussed on sustainable use of native grasslands ([McIntyre et al., 2002](#); [Wong and Dorrough, 2015](#)). Guides have been developed for farmers to enable management of native pastures ([Eddy, 2002](#); [Grassy Box Woodland CMN et al., 2011](#); [Kahn and Heard, 1997](#); [Langford et al., 2004](#); [Mokany et al., 2006](#); [Natural Resources Advisory Council, 2010](#)), and there is material focusing on conservation of flora

Fig. 12 Grassland plants are increasingly popular in the home garden; in the author's garden, Bungendore NSW. Photo: R. Rehwinkel.

and wildlife in the agricultural landscape (Barrett, 2000; Clarke et al., 1999; Dorrough et al., 2008; Lindenmayer et al., 2003; Michael et al., 2018).

Landcare, catchment groups and Local Land Services deliver information resources and advice to the agricultural sector on sustainable agriculture, often focussing on native grasslands as part of the farm landscape ('Ginninderra Catchment Group rural landcare' website; 'Molonglo Conservation sustainable land management' website; 'South East Local Land Services' website). GA's Whole of Paddock Rehabilitation program focuses on private grazing lands (Streatfield et al., 2010).

Conflicts between legislation and the agriculture sector

Clearing of woody vegetation including woodlands is continuing, despite legislation designed to limit this, and although data on clearing rates of grasslands is deficient, it is likely that grassland clearing is also continuing (Evans, 2015; 'Audit Office of NSW Managing native vegetation' website). Conflicts between threatened species and native vegetation policies and the agriculture sector have led to a review of the Australian Government legislation (Craik, 2018; 'The Land' website).

Conclusion

Grasslands and grassy woodlands remain amongst the most threatened ecosystems in SE Australia. Recognition of native grassy ecosystems by government agency ecologists and conservation managers has emerged, as has growing public interest, with community organizations and some landholders being particularly active. However, the conservation status of these systems remains poor, particularly that of grasslands. Australian and state government policies and legislative enforcement lag in some areas, with amongst SE Australian jurisdictions, perhaps only the ACT Government heading towards comprehensive grassland and grassy woodland conservation.

Abstract

The sclerophyll shrublands of southwestern Australia are a blend of graminoids, forbs, subshrubs and shrubs mostly < 2 m tall. They are renowned for their high species richness and endemism and spectacular floral displays in spring. The array of remarkable adaptations among root systems, leaves, flowers and fruits to the nutrient-impovertised soils, severe summer droughts and heat, intermittent crown fires and presence of unique pollinators, herbivores, granivores and dispersers matches the high species diversity. Phenology of the flora is controlled by both the mediterranean climate and the incidence of fires. Conservation of this special biome is threatened by land clearing in particular and the side effects of climate change.

Introduction

Vast areas of sclerophyll shrublands occur in the more coastal areas of southwestern Australia (Fig. 1). They stretch from just south of Shark Bay, 650 km north of Perth, to Cape Arid National Park, 800 km south-east of Perth, and (more patchily) 300 km east to Southern Cross, and cover about 13 million hectares (Lamont and Keith, 2017). These shrublands are a major repository of some of the world's rarest and most charismatic plants and animals in the presence of some of the world's poorest soils with extreme summer droughts and fires. They exhibit spectacular flora displays, have exceptional levels of species richness, turnover and endemism, and are the end product of tens of millions of years of nutritional poverty, episodic drought, recurrent fire and unique microbe-plant-animal interactions. They are of international significance for their contribution to biodiversity of the Earth, are an essential part of Australia's natural and cultural heritage, and are a unique resource for the biological sciences as human interference has remained minimal. In addition, they have utilitarian values in ecotourism, mineral sands, beekeeping, wildflower trade, source of propagules for rehabilitation and ornamental horticulture, and stabilizing greenhouse gases.

The sclerophyll shrublands thrive on nutrient-impovertised sands, sand over rock and among rock outcrops under a typical Mediterranean-type climate. The vegetation comprises exceptionally species-rich low heath to scrub/mallee heath, especially in the so-called northern and southern sandplains (Lamont et al., 1977). This vegetation type has been given the aboriginal name "kwongan," though it has not been widely adopted, with just heathlands or shrublands, or, more popularly, "wildflower country," generally used to describe this biome. The scrub-heath rises to low sclerophyll woodland with a heathy understorey in the Perth Coastal Plain that has a higher winter rainfall than the northern and southern sandplains (Tsakalos et al., 2019). Freshwater lakes are dotted through the biome and it is traversed by many creeks and a few rivers, notably the Moore, Swan and Kalgan, that only flow in winter-spring. Much of the area has been cleared for farming since 1960, despite the poor soils, and, to a lesser extent, for housing, roads, light industry, and mining for heavy minerals. However, this unique flora is still well represented in reserves and national parks and much intact Crown land remains.

Climate and Soils

The climate is a typical Mediterranean-type, with long hot summers and mild wet winters (Fig. 2). Cloudless skies are typical over summer. Snow is unknown (it is rarely recorded in the peaks of the Stirling Ranges in the south of the biome). The weather is milder in the south (moderate mediterranean, with pan evaporation typically exceeding rainfall by four times) and more extreme in the north and east (dry warm mediterranean, with evaporation exceeding rainfall by about eight times) (Table 1). Rainfall is typically 300–600 mm pa but can rise to 1200 mm in the uplands (Darling Scarp, Stirling Range). Mean rainfall has declined by 15% since 1970 and is not taken into account by these figures. Minimum temperatures average a minimum of 6(south)-12(north)°C in the winter months of June-August and a maximum of 25(south)-37(north)°C in the summer months of January-February

Fig. 1 Distribution of sclerophyll shrublands in SW Australia (in black) framed by the three major biogeographic regions, with the northern and southern sandplains characteristic of the upper and lower regions respectively. The inset shows the area highlighted (square) relative to the rest of Australia. Adapted from Lamont, B. B. and Keith, D. A. (2017). Heathlands and associated shrublands. In: Keith, D. A. (ed.) *Vegetation of Australia*, 3rd edn. Cambridge: Cambridge University Press. pp. 339–368, reprinted with permission.

Fig. 2 Monthly rainfall and minimum and maximum temperatures (May 2006 to May 2007) for Perth (29.92°S 115.87°E) (solid line) and Eneabba (29.82°S 115.27°S) (dashed line), 300 km north of Perth, for two sandplain locations in southwestern Australia. Data obtained from the Bureau of Meteorology, Australia (www.bom.gov.au) and plotted by B. B. Lamont.

(Fig. 2). The mean relative humidity at 15.00 h in January is 60(coastal)-30(inland)%. Several days above 40°C are common in summer with relative humidity reaching < 15%. Most areas have < 50 days of mild frost a year, but it may reach 100 days inland (data collated from Lamont and Connell, 1996).

The mediterranean climate in Western Australia probably first arose 1000 km north of its current center as the Australian continent gradually drifted toward the equator after separating from Antarctica 34 million years ago (Lamont and He, 2017). It then migrated south as Australia continued north so that a mediterranean climate was already widespread in the southwest by 20–10 million years ago. However, it is likely that sclerophyll shrublands long preceded the mediterranean climate, as many typical plant groups originated in the Cretaceous period over 50 million years earlier. Thus, the environmental conditions would have been uniformly wet, hot and fire-prone (due to the high oxygen levels prevailing then) but, as now, located in the most nutrient-impovertished sites, leached sands, and laterites and rock outcrops (see under "Fire").

Table 1 Sclerophyll shrublands within the natural regions of southwestern Australia including their climates, annual rainfall, length of growing season (for crops), and dominant vegetation.

Natural region	Climate	Annual rainfall (mm)	Length hot dry season (months)	Dominant vegetation
Northern sandplains	Dry warm mediterranean	300–500	7–8	Scrub-heath interspersed with mallees, dominated by sclerophyllous Myrtaceae, Proteaceae, Fabaceae, Ericaceae, Restionaceae; <i>Acacia-Allocasuarina</i> thickets inland
Swan coastal plain	Warm mediterranean	600–1000	5–6	<i>Banksia</i> low woodland with sclerophyll shrub understorey, <i>Melaleuca</i> swamps in lowlands, eucalypt woodlands on coast and eastern edge
Wheatbelt	Dry warm mediterranean	300–650	7–8	Eucalypt woodlands, <i>Acacia-Allocasuarina</i> thickets, patches of scrub-heath
Mallee	Dry warm mediterranean	300–500	7–8	Eucalypt scrub-heath and woodland, understorey of sclerophyllous shrubs
Southern sandplains	Moderate mediterranean	500–700	5–6	Scrub-heath or mallee-heath dominated by sclerophyllous Myrtaceae, Proteaceae, Fabaceae, Ericaceae, Restionaceae

Collated from Groom, P. G. and Lamont, B. B. (2015a). Evolution and diversity of the flora. In *Plant Life of Southwestern Australia: Adaptations for Survival*. pp. 6–29. Warsaw: De Gruyter Open.

The landforms are usually undulating dunes rising little more than 5 m above the flat swales, sometimes interspersed with prominent uplands of laterite, sand over laterite, tamala limestone, sand over limestone, quartzite, metaschists or gneissic granite. The deep sands are well drained but because they store so much water they support the tallest vegetation with the greatest biomass per unit area (Fig. 3). The rock outcrops too are well drained but the restricted availability of soil, as a source of water and nutrients, means that they can only carry low heath. Shallow sand over a hardpan of clay-silt in lowlands or uplands with sand over laterite, limestone or granite too are resource-stressed and can also only support low heath. Some lowland swales or local depressions, some spring fed, are waterlogged bogs in winter-spring that are water-stressed in summer and again can only support low vegetation, often bearing endemic species, such as *Beaufortia squarrosa* (Myrtaceae).

Soils are typically slightly acid (pH 5.8–6.5) but may exceed a pH of 7.0 on calcareous dunes and outcrops. The sands are renowned for their nutrient impoverishment, especially the low levels of phosphorus ($1\text{--}4\text{ mg kg}^{-1}$), considered among the lowest in the world, but also nitrogen, potassium and the micronutrients, especially zinc, copper, boron, and sometimes molybdenum (Table 2). This has resulted from millions of years of fires and leaching without landscape rejuvenation. In a three-way interaction trial, wild oats failed to thrive unless phosphorus, nitrogen and potassium were added to Eneabba sand (Lamont, 1995) that supports scrub-heath which is equally renowned for its high species diversity (Table 2; Lamont et al., 1977). Note the tendency

Fig. 3 Stylized vegetation profile, including root systems, of sclerophyll vegetation on deep sandy dunes (crest, left) and shallow sands over clay-silt associated with a deeper laterite deposit (swale, right). This interspersed of scrub-heath and low heath is typical of the dune complex in the northern sandplains. Even though two such sites (on which the above profile is based) were just 300 m apart, only 41% of their species were in common (Table 2). From Lamont, B. B. and Keith, D. A. (2017). Heathlands and associated shrublands. In: Keith, D. A. (ed.) *Vegetation of Australia*. 3rd edn. Cambridge: Cambridge University Press. pp. 339–368, reprinted with permission.

Table 2 Details on the shrubland floras present in five representative plots in the Eneabba Plain, southwestern Australia.

Substrate	Coastal limestone	Laterite upland	Low dune (flat)	Interdune lowland (swale)	High dune (crest)
Shrubland type	Scrub-heath	Low heath	Scrub-heath	Low heath	Scrub/mallee heath
Perennial species in 40 × 40 m ²	72	93	101	109	114
Unique species (%)	47	26	8	15	9
Mean plant density (m ⁻²)	6.7	15.2	8.8	14.3	6.6
Mean species density (m ⁻²)	5	10	8	11	6
Species diversity based on cover (H')	1.41	1.47	1.60	1.66	1.53
Most abundant species (family) based on cover	<i>Hibbertia hypericoides</i> (Dilleniaceae) (14.7%)	<i>Ecdeiocolea monostachya</i> (Restionaceae) (11.3%)	<i>Banksia attenuata</i> (Proteaceae) (15.7%)	<i>Lepidobolus preissianus</i> (Cyperaceae) (5.9%)	<i>Banksia hookeriana</i> (Proteaceae) (15.0%)
Next most abundant species	<i>Acacia spathulifolia</i> (Fabaceae)	<i>Georgeantha hexandra</i> (Restionaceae)	<i>Melaleuca leuropoma</i> (Myrtaceae)	<i>Ecdeiocolea monostachya</i> (Restionaceae)	<i>Banksia attenuata</i> (Proteaceae)
Next most abundant species	<i>Melaleuca leuropoma</i> (Myrtaceae)	<i>Allocasuarina microstachya</i> (Casuarinaceae)	<i>Hakea polyanthema</i> (Proteaceae)	<i>Mesomelaena stygia</i> (Cyperaceae)	<i>Hibbertia</i> aff. <i>hypericoides</i> (Dilleniaceae)
Next most abundant species	<i>Banksia leptophylla</i> (Proteaceae)	<i>Hibbertia hypericoides</i> (Dilleniaceae)	<i>Desmocladius semiplanus</i> (Myrtaceae)	<i>Beaufortia elegans</i> (Myrtaceae)	<i>Adenanthos cygnorum</i> (Proteaceae)
Next most abundant species	<i>Labichea cassioides</i> (Fabaceae) (8.7%)	<i>Melaleuca scabra</i> (Myrtaceae) (3.3%)	<i>Cassytha pubescens</i> (Lauraceae) (8.2%)	<i>Banksia (Dryandra) shuttleworthiana</i> (Proteaceae) (3.3%)	<i>Xylomelum angustifolium</i> (Proteaceae) (6.0%)
Postfire resprouting species (%)	67	88	79	81	69
Interfire annuals (%)	17	1	2	4	2
Species with plant-held seeds (%)	19	24	25	28	26
Species with soil-stored seeds (%)	81	76	75	71	73
Surface soil pH (in water)	6.7	6.1	6.0	6.2	6.2
Colwell's available P (mg kg ⁻¹)	4.0	4.0	2.8	3.7	2.9

Data obtained from Enright, N. J., Mosner, E., Miller, B. P., Johnson, N. & Lamont, B. B. (2007). Soil versus canopy seed storage and plant species coexistence in species-rich shrublands of southwestern Australia. *Ecology* 88, 2292–2304.; Perry, G. L. W., Enright, N. J., Miller, B. P. and Lamont, B. B. (2008). Spatial patterns in species-rich Mediterranean-type shrublands of southwestern Australia. *Journal of Vegetation Science* 19: 705–716; Herath, D. N., Lamont, B. B., Enright, N. J. and Miller, B. P. (2009). Comparison of postmine rehabilitated and natural shrubland communities in southwestern Australia. *Restoration Ecology* 17, 577–585; Herath, D. N. and Lamont, B. B. (2009). Persistence of resprouting species after fire in natural and post-mine restored shrublands in southwestern Australia. *Applied Vegetation Science* 12: 451–458. The three exotic species present overall have been omitted from the numbers. See the original papers for variation about the means given here. Compiled by B.B. Lamont.

for species richness to increase as availability of all nutrients declined in the studies reported in Table 2. The porous sands and moderate rainfall ensure that dryland salinity is unknown here, unlike the silty loam soils to the east of the region.

Vegetation and Flora

The vegetation can be divided into: (a) low heath, species-rich sclerophyllous subshrubs, broad-leaved creepers and leafless graminoids to a height of 0.5 m, (b) heath, similar but shrubs reach a height of 1.5 m, and (c) scrub/mallee heath, heath with some emergent shrubs (scrub) and occasional trees (mallees) reaching 4 m tall but typically < 2 m. Families that are represented elsewhere as

Fig. 4 Selected examples of sclerophyll shrublands in southwestern Australia (sites proceed from north to south to east). (A) Spring flowering of low heath in Kalbarri National Park in the most northerly sandplains with *Melaleuca* aff. *scabra* (Myrtaceae, red) and *Conospermum stoechadis* (Proteaceae, 1 m tall, white) in flower; (B) bird-pollinated *Banksia hookeriana* (Proteaceae), 1.3 m tall, flowering from seed 5 years after fire in Yordanogo Reserve, northern sandplains, showing a positive edge effect beside the road (Lamont et al., 1994); (C) scrub-heath in Trigg Point (hill on right) Reserve, Eneabba with *Banksia attenuata* (Proteaceae, left), and *Lambertia formosa* (Proteaceae, right), 1.6 m tall, with *Xylomelum angustifolium* (Proteaceae) with white fruits held on plant in midground until opened by fire heat; (D) Scrub-heath on calcareous coastal dune (outcropping limestone in foreground) at Jurien Bay, with *Melaleuca huegelii* (Myrtaceae, white), 1.6 m tall, and *Banksia* (*Dryandra*) *sessilis* (Proteaceae, yellow) in foreground, with planted marram grass (*Ammophila arenaria*) in midground; (E) low heath with emergent grasstrees (*Xanthorrhoea acanthostachya*, Asphodelaceae), 1–1.5 m tall, sand-covered sandstone downslope from lateritic breakaway on left (where crouching person can be seen) in the

shrubs and trees (Myrtaceae, Proteaceae, Fabaceae) exist here as numerous subshrubs and ground creepers, some even clonal. Images of representative shrubland sclerophyll types are given in Fig. 4 and show the profound effect of substrate, climate and landscape location on the type of vegetation that can be supported. Even adjacent dunes and the intervening swales can have quite different physiognomies and floristics because of substrate effects. These vegetation types are best represented in the so-called northern and southern sandplain country (Table 1). The shrubland continues beneath the banksia and eucalypt woodlands and forests where soils are more fertile and the rainfall is higher. The sclerophyll shrublands are the heart of the high species diversity of southwestern (the SouthWest) Australia: although they cover only 10% of its area, these shrublands account for over 4250 (50%) of its plant species. The SouthWest in turn covers only 5% of Australia yet accounts for 30% of its species.

The major plant families in Australia reach their peak representation in the sandplain country. These include the woody Myrtaceae, subfamily Leptospermoideae, especially *Melaleuca* that has now been enlarged to 440 species Australia-wide; Proteaceae, especially *Grevillea* and its sister *Hakea* (together comprising 300 species in the SouthWest) and *Banksia* with 80 species. Paraphyletic rules indicate that *Banksia* should include *Dryandra*, endemic to the SouthWest with an additional 100 species, although there has been resistance to such lumping as they are easily distinguished in the field. This is followed by the legumes, especially *Acacia* (subfamily Mimosoideae, 440 species in the SouthWest) and *Gompholobium* (subfamily Faboideae), and Ericaceae (subfamily Epacridoideae), especially the essentially endemic *Leucopogon* with 210 species here. Mallee eucalypts, with gigantic lignotubers, are widespread, especially in the southern sandplains.

The grass-like Restionaceae and Cyperaceae are prominent although the true grasses, Poaceae, are not. Creeping undershrubs, such as *Dampiera* (Goodeniaceae), are also conspicuous. The geophytic terrestrial orchids, especially *Caladenia* with 150 species in the SouthWest, are widespread though many species are highly localized. Small herbs, such as the trigger plants, *Stylidium* (210 species), and carnivorous droseras (> 100 species), are nowhere better represented on a world scale. Annuals, essentially the daisies, Asteraceae, and the tiny Centrolepidaceae contribute little to species diversity or biomass but persist, and are especially evident after fire. Most notable is the annual kangaroo grass, *Austrostipa compressa*, that may form a sward in the first year after fire and be virtually absent by the next year. Herbaceous weeds, especially from South Africa and the Mediterranean Basin, have spread throughout the metropolitan and farming areas, though nature reserves and unallocated lands remain weed free (Table 2).

While species richness is exceptional at the broad scale (gamma diversity), it is also exceptional at the fine scale (alpha diversity). Despite the fact that 95% of the species in a stand of vegetation are evergreen perennials, every square meter of the interdunal low heaths typically contains 14 evergreen plants and these belong to 11 species (up to 37 plants and 21 species per individual m²), so that an area of just 40 × 40 m² contains 23,000 plants and 109 species (Table 2). This is because of the small growth form of most plants (graminoids, herbs, and subshrubs) that allows for high species packing given a large species pool (Perry et al., 2009; Lamont and Keith, 2017). In addition, their low projective cover [few leaves (or none) and these leaves are small (leptophylls), needle-like or vertically oriented] such that their crowns readily overlap and plants can intermingle. Of course, in taller vegetation the number of plants reduces accordingly but not necessarily species richness because some large plants, such as *Eucalyptus tottiana*, can facilitate the presence of others, such as *Stachystemon axillaris* (Groom and Lamont, 2015a,b). Another feature of this flora is the prodigious diversification that has occurred in selected, well-adapted genera. Thus, for the five 40 × 40 m² plots in representative shrubland types in the Eneabba sandplain described in Table 2, *Banksia* (mostly in the form of *Dryandra*) is represented by 14 species, *Hakea* by 11, *Leucopogon* by 10, *Stylidium* by 10, *Lepidosperma* (Cyperaceae) by 10, and *Conostylis* (Haemodoraceae) by 6 species. We located one site in the Fitzgerald River National Park that contained 7 *Hakea* species within an area of just 10 × 10 m² (Lamont and Groom, unpublished). See Table 2 for other well-represented species in this subbiome.

Fire

Sclerophyll shrublands are highly flammable in the dry season, summer-autumn (Fig. 5). They currently burn at 10–20-year intervals but they can carry a fire again within 5 years while stands that escape fire for 40 years or more are almost unknown. Anthropogenic causes have taken over from lightning as the main ignition source. All species have some traits that enable them to survive fire as a result of their lineage's long history of fire-proneness. It has been shown that fire itself (in the form of heat, source of

← Gairdner Range, Mt. Lesueur National Park—the plants here have the smallest growth forms and by the far the highest species density among the eight sites shown here; (F) spring flowering of heath on Cenozoic laterite with outcropping Precambrian gneissic granite (right) at Crystal Brook Reserve, 15 km east of Perth; over 80% of species seen flowering in the image (*Grevillea*, *Hemigenia*, *Acacia*, *Diplopeltis*, *Burchardia*) regenerated 7 years ago from soil-stored seeds; the remainder [*Hakea*, *Allocasuarina*, *Isopogon*, *Banksia* (*Dryandra*)] recovered from plant-stored seeds; the one exception is *Xanthorrhoea preissii*, still showing spike remnants from its fire-stimulated flowering at that time, whose seeds must germinate the first winter after flowering or perish; (G) thick scrub to 4 m tall that suppresses smaller growth forms on neutral sands Milyearup, Scott River with *X. preissii*, *Banksia grandis* and the rare *Lambertia orbifolia* (Proteaceae) in the midground, with scattered trees of *Agonis*, *Melaleuca* and *Eucalyptus* (all Myrtaceae) and *Acacia*; the conical dunes in the background support low heath with some scrub-heath (this area is poorly known botanically); (H) scrub-heath near Cheynes Beach, 160 km north-east of Albany, on sand over gneissic granite with low mallee eucalypt (foreground), *Melaleuca*, *Calothamnus* (Myrtaceae) and *Adenanthos sericeus* (Proteaceae, upper left), 2 m tall; note pruning of *Banksia praemorsa* on the right that is otherwise protected from the salt-laden winds by the pinnacle of granite in the almost absence of soil. The water visible in the backgrounds of C–E is the Indian Ocean, and that in H is the Southern Ocean. Photos taken by B. B. Lamont, except A, donated by J. S. Beard.

Fig. 5 (A) Crown fire in scrub-heath at Yardanogo Reserve, southwestern Australia. Flames are consuming a 2-m tall, fire-killed *Banksia hookeriana*—note the cones, which have retained their highly combustible florets, are igniting and they will later release their seeds stored in the heat-resistant follicles. (B) *Banksia menziesii*, 0.9 m tall and at the same location, recovering from fire 3 years ago via its massive lignotuber and already producing bird-pollinated flower heads. Note the open follicles (arrowed) on cones retained on the dead prefire stems and white indumentum on the stomate-bearing underside of the leaves and their highly reflective upper surfaces. Photos taken by B. B. Lamont.

mutagenic organic chemicals or by concentrating mutagenic chemicals already in the environment) may be a potent mutagenic agent with the potential to induce trait change and species diversification (He and Lamont, 2018). There is increasing evidence that the presence of fire and the origin of fire-related traits among many prominent shrubland families can be traced back to the Mid-Upper Cretaceous Period (100–70 million years ago) (Lamont et al., 2018). This means that pockets of sclerophyll shrublands/woodlands may have existed in the Southwest, and through much of Australia, at that time. While it is likely that a uniform rainfall, perhaps with a summer maximum, prevailed then, seasonality would not have controlled the incidence of fires like today because atmospheric oxygen levels were so high that plant matter was much more combustible. Sclerophylly would have been promoted by poor soils and rocky substrates even then. The slow rates of decay would lead to considerable fuel buildup, and the frequent lightning strikes associated with the high rainfall, especially in the exposed drier uplands, together with the high oxygen, were a combination of selective forces that would have promoted the evolution of many fire-adapted traits.

Of particular interest are the fire-stimulated resprouters that account for 65–90% of species in local floras (Table 2). These resprout from the major stems via numerous sunken epicormic buds among taller plants, from a swollen rootstock (lignotuber, Fig. 5) or root crown via sunken accessory buds among most shrubs and subshrubs, and from creeping underground stems (rhizomes) via axillary buds among graminoids and herbs, or suckering from lateral roots among a few shrubs and herbs (Pausas et al., 2018). An exception are the widespread grass-trees, *Xanthorrhoea* (Asphodelaceae) and *Kingia australis* (Dasypogonaceae): their terminal buds are well insulated from fire heat by the mantle of leaves wrapped around the apex and they just keep growing at an accelerated rate after fire. With their slow generation times, 300–500 years or more, and low seed production, it is surprising that speciation of resprouters has kept pace with fire-killed species (a new generation every time there is a fire and high seed production) in the sandplains. Clonal plants are the longest lived and it has been estimated that the creeping shrub, *Banksia candolleana*, for example, may survive for 1100 years. Although controversial, there is increasing evidence that nonsex-related mutations, which are more likely to occur in older plants, may not only cause low seed set in the first place but may sometimes lead to genetically distinct offspring (Fowler et al., 2018).

On-plant seed storage is called serotiny. Not only is southwestern Australia the world center of diversification for this reproductive trait, but it also peaks in the sclerophyll shrublands. The most prominent species in shrublands are serotinous and it accounts for 20–30% of local floras (Table 2). The seeds are retained in woody fruits (Proteaceae—*Banksia* (follicles held in cones, Fig. 5), *Hakea*, *Xylomelum*, Myrtaceae—*Eucalyptus*, *Melaleuca*, *Leptospermum*, *Beaufortia*, *Calothamnus*) or cones (Cupressaceae—*Callitris*) or winged, single-seeded fruits in cones (Casuarinaceae—*Allocasuarina*, Proteaceae—*Petrophile*, *Isopogon*, Restionaceae—*Lyginia*). Fire heat from summer-autumn fires releases seeds from their supporting structures and they arrive on an ideal surface for germination and recruitment following winter-spring rains. Nutrients build up in the seeds while stored on the plant. While the seeds stored by *Banksia hookeriana* only account for 0.5% of its aboveground biomass, they contain 48% of its phosphorus, 24% of its nitrogen and 4% of its potassium (Lamont and Groom, 1998). This gives the seedlings a head start once the seeds are released into the nutrient-depleted sands following fire.

The remaining species (70–80%) release their seeds once they are mature and they are stored in the soil until the next fire (Table 2). They are either stimulated to germinate by heat (hard seeds of the Fabaceae, such as *Acacia*, *Daviesia*, *Hovea*, *Gompholobium*, *Bossiaea*, *Oxylobium*, *Albizia*, *Templetonia*, and other families, such as Surianaceae—*Stylobasium*, Polygalaceae—*Comesperma*) or smoke (softer seeds of grasses in *Austrostipa* and Restionaceae—*Desmocladius*, *Lepidobolus*, *Stylidium*; Anthericaceae; Haemodoraceae—*Anigozanthos*, Iridaceae; Dilleniaceae; Euphorbiaceae—*Stachystemon*; Ericaceae; Goodeniaceae; Proteaceae—*Grevillea* only; Rutaceae—*Pimelea*; Violaceae—*Hybanthus*). Only 1–2% of species release their seeds at maturity that must germinate the first winter or perish but do include the ecologically important grasstrees—*Xanthorrhoea* and *Kingia*, the unique *Nuytsia floribunda* (Loranthaceae)—the only mistletoe with winged fruits and one of the world's outstanding flowering small trees, and *Macrozamia*—typical of other cycads, its emu-dispersed seeds must germinate in the second year after release or die. These shrublands are also centers of diversification for ants and the world's greatest concentration of ant-dispersed/buried seeds exists here.

Another feature of this flora is fire-stimulated flowering (FSF): about 10% of species flower only in the 1–2 years after fire (obligate) or peak at that time (facultative). FSF is particularly well represented among geophytes, especially terrestrial orchids and droseras, but, unlike fire-prone floras in other climate types and continents, resprouting woody shrubs and subshrubs are also prominent. With 24 species so far recorded with FSF, *Caladenia* (Orchidaceae) is the best represented genus but other speciose orchid genera are *Diuris*, *Cyanicula*, and *Prasophyllum* (Lamont and Downes, 2011). Graminoids include *Lomandra* and *Dasyopogon* (Dasyopogonaceae) and a few rhizomatous grasses, geophytes such as *Drosera* (eight species), *Burchardia* (Colchicaceae), *Thysanotus* (Asparagaceae), *Haemodorum* and *Conostylis* (Haemodoraceae), forbs include clonal *Anigozanthos* and *Macropidia* (Haemodoraceae) and a few *Stylidium*. (Sub)shrubs include the floriferous *Pileanthus* and *Verticordia grandis* (Groom and Lamont, 2015b) (Myrtaceae), *Stirlingia* and *Conospermum* (Proteaceae). The cycads (*Macrozamia*) also show fire-stimulated coning that is almost obligate. The most conspicuous group with FSF are the grasstrees, *Xanthorrhoea* and *Kingia*. The most remarkable of all is the clonal small tree, *Nuytsia floribunda*, emergent in all types of heath, whose masses of orange blooms emerge in late spring from blackened trunks before leaf production has commenced (called protanthly) (Lamont and Downes, 2011).

Phenology

Seeds germinate the first winter after summer-autumn fires and seedlings grow rapidly over spring until summer heat and drought settle in. Small-seeded species produce small seedlings that are drought tolerant and have small or needle leaves that reduce the heat load. Large-seeded (> 20 mg) species produce large seedlings that develop a long taproot at the expense of laterals: by summer, a 15-cm tall plant may possess a root system exceeding a depth of 200 cm that helps it maintain contact with soil water. Nevertheless, almost all young plants spend some months below the wilting point and survival by autumn seldom exceeds 50%, including fitful herbivory by kangaroos and grasshoppers (Lamont and Groom, 1998). Attrition continues over the years so that eventually self-replacement by 15 years (when the next fire is likely) may have taken 50–200 seeds from the original parent plants. Once established, forbs and subshrubs can only flower then grow vegetatively during the wet season, while deep-rooted shrubs and small trees continue to flower then grow well into summer, some showing negligible drought stress at this time. Annuals and geophytes, such as droseras, are the first to appear in winter and to dieback by early summer. *Xanthorrhoea* is unusual as it never stops growing and leaf growth may even accelerate in response to summer rains (Lamont et al., 2004).

Fire-surviving plants break this cycle by starting to recover immediately postfire so that substantial regrowth may have occurred by up to 6 months before the wet season begins. Geophytes and some forbs and shrubs may even be stimulated to flower in response to fire, though most flowering is retarded by a few years as growth and flowering gradually increase up to an asymptote some 15–20 years after the fire. Some subshrubs and forbs may only survive for 5–10 years, but those reaching 2 m or so typically survive for 40–50 years. Unless strongly serotinous, all species release their seeds in response to the drying conditions of summer. Some species benefit from the stronger winds of autumn to lift the seeds or winged fruits from their supporting structures (*Nuytsia*, *Xylomelum*, *Hakea*) while others require the wet-dry cycles associated with autumn rains to open the valves or scales sufficiently to release their contents (*Banksia*, *Petrophile*, *Allocasuarina*).

Roots only grow in the wet season. Root growth in the surface humus layer is early and prolific. The Proteaceae (except *Persea*, although this genus has rootlets with exceptionally long root hairs) and some legumes develop hairy root clusters (proteoid roots, Fig. 6B) that adhere to the decomposing litter and soil particles, a major source of phosphorus and micronutrients in these highly leached sands (Lamont, 2003). They act by secreting organic acids and enzymes that solubilize inorganic phosphates in particular. As a result, an estimated 80% of the root system lies in the uppermost 10 cm of soil (Lamont and Keith, 2017). The remaining 70–90% of species usually possess fungal threads attached to their rootlets (mycorrhizas) that enhance nutrient uptake in a similar way. The most important groups of plants are the Myrtaceae (*Eucalyptus*, *Melaleuca*) and some legumes (*Gastrolobium*) with ectomycorrhizas associated with higher (puffball) fungi. Almost all other plants possess endomycorrhizas, notably *Hibbertia* (Dilleniaceae), *Caladenia* (Orchidaceae), and *Leucopogon* (Ericaceae), all associated with different, but less advanced, fungal partners. Fixation of soil-stored free nitrogen, especially in response to the extra nutrients released by fire that promotes vegetative growth, occurs among all faboid and mimosoid legumes here via perennial root nodules (rhizobacteria), cycads via coralloid roots (cyanobacteria) and waterlogged casuarinas via actinorhizas (*Frankia* fungi). It has long been known that the belowground nutrient uptake mechanisms and their associated microflora in the sclerophyll shrublands are as diverse as the aboveground macroflora (Lamont, 1982).

Fig. 6 With 100 species and 7 extra subspecies, including four species yet to be named and all but 4 endemic to the sclerophyll shrublands/woodlands of southwestern Australia, *Hakea* (Proteaceae) is the archetype genus in this biome. It is also regarded as the world's most sclerophyllous clade (Lamont et al., 2015). (A) *Hakea francisiana* showing its 12-cm long raceme held on a strong stem produced the previous year that enables meliphagid birds to perch while probing for nectar (visible as beads in the image) and inadvertently picking up pollen from the protruding presenters (most are still in the “looped” condition here) or depositing pollen once the stigmatic cleft emerges the next day. Typical of bird-pollinated flowers, the inflorescence is reddish and high in cyanoglycosides that deter herbivory from other birds such as cockatoos and emus (Hanley et al., 2009). Note the upward-pointing, isobilateral leaves that have twisted vertically and serve to limit light reception during the hottest part of the day. (B) Surface lateral root of *Hakea incrassata* bearing a sequence of three proteoid root clusters (all hakeas and all taxa, but *Persoonia*, in the Proteaceae produce these bottlebrush clusters of hairy rootlets). They are ephemeral, absorbing water and poorly mobile nutrients, especially phosphates and molybdenates, during the wet season, and take the place of mycorrhizas common in other plant groups here (Lamont, 2003). Photos taken by B. B. Lamont.

Flowering

Some flowering occurs throughout the year in the sclerophyll shrublands but they are renowned for their spectacular displays of flowers in spring (Figs. 4–7). This coincides with high demand from insect pollinators that are most active in moderately warm weather and the breeding season of bird and mammal pollinators. The range of adaptations to the presence of these three groups of pollinators is perhaps unparalleled in the world, the three syndromes sometimes even present in the same genus (Fig. 7). Visitors to the flora comment on the abundance of blue-mauve flowers, including *Dampiera* such as *D. wellsi* (Goodeniaceae, 60 species in SW Australia), *Lechenaultia floribunda* (Goodeniaceae), *Cyanicula* (Orchidaceae), *Trachymene caerulea* (Araliaceae), *Patersonia occidentalis* (Iridaceae) and *Hakea lehmanniana*. These attract insect pollinators that see well in the ultraviolet range, but many small-flowered species with little nectar production have other colors (white, pink, yellow, orange, red, green). The mammal-pollinated species tend to have inflorescences concealed in the crown, and are dull-colored (honey yellow, brown, Fig. 7) consistent with their rodent and marsupial pollinators that tend to be active only at night, and emit a musky odor and so much nectar that it often drips to the ground acting as a trail to the inflorescences. The bird-pollinated inflorescences are usually brightly colored, especially red, and held above the crown or away from the stem, lack any odor and also produce copious nectar.

The terrestrial orchids have produced the most bizarre pollination syndromes, varying from the nonrewarding blue flowers of several *Thelymitra* species that mimic rewarding blue flowers in other families, to the fungal-gnat-pollinated underground orchid, *Rhizanthella gardneri*, that emits a putrid odor thought to mimic the spore-bearing bodies of mycorrhizal fungi. Of special interest are the wasp-pollinated orchids, *Drakaea*, *Paracaleana*, *Cryptostylis* and *Spiculaea*, that emit pheromones attractive to particular male thynnid or ichneumonid wasps that attempt to copulate with the head of the labellum whose appearance mimics the corresponding female wasp—the labellum is articulated and it is then triggered to swing the wasp back to the androgynoeium where pollen is either received or donated. (All these pollination syndromes are fully described in Groom and Lamont, 2015c).

Other special features of this flora include: (a) protandry—the anthers mature before the stigma that promotes outbreeding and is universal in such major families as Myrtaceae, Proteaceae, Goodeniaceae, Stylidiaceae (SW Australia is the world center of distribution of the “trigger” plants with 210 species, predominantly in the heathlands), Myoporaceae and Thymelaeaceae; (b) flower color change (usually cream to red) as they mature that promotes pollination efficiency; (c) though most species accept a wide range of pollinators because of their high nectar production that attracts the three pollinator groups, there are

Fig. 7 Three species of *Banksia* adapted to the three types of pollinators present in SW Australian shrublands: left: *B. lemanniana* (bloom 12 cm long) with *Cryptocheilus* wasps; middle: *B. prionotes* (bloom 15 cm long, tree present in moister sites in northern sandplains) with white-cheeked honeyeater that uses the flower head as a landing platform; right: *B. tricuspis* (bloom 15 cm long, restricted to the Lesueur National Park) with honey possum [the only mammal (marsupial) with a specially constructed tongue for gathering pollen as well as nectar]—note the hooked styles that hold pollen at their tips and scrape against the head of this tiny marsupial. Photos taken by B. B. Lamont, Jiri Lochman and S. van Leeuwen respectively.

many species with pollinator-specific flowers, such as bee-pollinated verticordias; and (d) the presence of poisonous compounds (cyanide-bearing glycosides—*Hakea*, *Grevillea*, fluoroacetate—*Gastrolobium*) within inflorescences exposed to bird pollinators (and hence bird florivores) versus small inflorescences concealed among spinescent foliage that are insect-pollinated and lack such compounds (Hanley et al., 2009).

Leaves

The distinctive, leathery-stiff texture of leaves (sclerophylly) is characteristic of this biome (70% of species). Indeed, SW Australia has the most sclerophyllous flora in the world, attributed to both the nutrient scarcity and severe summer droughts, so that the level of sclerophylly is highest in low heath and in the northern sandplains (Lamont et al., 2002). *Hakea*, with 100 species here, is the world's most sclerophyllous genus. Notable species include *H. clavata*, occurring on granite outcrops near Esperance, whose leaves are up to 5 mm thick (no hard-leaved species anywhere is thicker)—thickness is a drought adaptation. *H. oldfieldii* has the highest dry leaf density at 1.0 mg mm^{-3} (no species anywhere has a harder leaf due to its high concentration of lignified tissues that stop leaf collapse when below turgor)—density is a low-nutrient adaptation. For comparison, hardwood timbers have a dry density of about 0.8 mg mm^{-3} . Winter deciduous plants, characterized by their low leaf hardness, are unknown, though most plants drop some or all of their old leaves at the start of summer (aestivation) that reduces the transpirational surface. Even so, the low nutrient availability means that leaf turnover risks the loss of nutrients already absorbed so that again this flora is renowned for its leaf longevity (40% greater than 2 years), with a record of 13 years in the prostrate *Banksia gardneri* whose highly divided vertical leaves act like stems. Nevertheless, many annuals, geophytes, forbs and some shrubs have relatively mesomorphic leaves (30% of species) and the oldest are dropped annually (20%). Leaf succulence is rare (3%), and includes the creeping *Carpobrotus* (Aizoaceae) on calcareous soils. (A full discussion on leaf properties is given in Groom and Lamont, 2015d).

The leaves are also known for their small size: about 50% of the species in a typical heath site have leaves under an area of $5 \times 5 \text{ mm}^2$ (leptophylly) with almost no species exceeding $75 \times 75 \text{ mm}^2$ (mesophylly). Odd leaf shapes include scale-like (10%), needle-like (25%), strap-like (35%), and highly dissected (10%). Loss of the leaf blade retaining just the petiole (phyllode) is the norm among legumes, with the phyllodes continuing down the flattened green stem (phylloclade) in a few species that is possibly unique to this flora. Absence of leaves is notable: species of *Daviesia* and *Jacksonia* (Fabaceae) and *Exocarpos* (Santalaceae), all Casuarinaceae (20 shrubland species) and all Restionaceae, the most prominent graminoid in the flora. It is interesting to note that most taxa without normal leaf lamina development contain higher than average levels of nutrients and this might reduce their attractiveness to herbivores as well as reduce their heat load and need for nutrient cycling. Another remarkable feature is the preponderance of heterophylly (different leaf types within the same plant) that is essentially a heteroblastic process, with juvenile leaves tending to be more mesomorphic and the adult leaves (associated with flowering) more sclerophyllous. This process is usually repeated among branches resprouting after fire. Heterophylly is best known among the legumes, especially *Acacia*, and eucalypts and almost universal in the Proteaceae. Heteroblasty may also occur on an annual basis, of which the most outstanding example

is *Hakea trifurcata* (Proteaceae) that does not commence production of its broad, highly incurved leaves until it is able to flower. Its alternating seasonal broad-needle leaf sequence has been used to support other evidence that a mediterranean climate has existed in southwestern Australia since the Miocene, though greatly restricted during the ice ages of the Pleistocene (Lamont and He, 2017). This species is one of at least 12 hakeas whose leaves appear to mimic or shield the fruits from granivores. They appear to be ineffective against black cockatoos (unlike the exceptionally large woody fruits produced by some other species in this genus) and may instead to be aimed at insect granivores (beetles, moths) that are usually night active and have poor eyesight so that they are less likely to oviposit on the more vulnerable fruits that remain green (Lamont et al., 2016).

Conservation and Management

The major threats to the distribution and biodiversity of the sclerophyll shrublands in SW Australia are land clearing with habitat fragmentation, weed invasion, climate change, suboptimal fire regimes, plant pathogens, wildflower picking, and eutrophication. Land clearing is the most significant but could easily be controlled through appropriate legislation. Consider the charismatic *Banksia hookeriana*, restricted to a 15 × 120 km area in the northern sandplains and whose biology/ecology are possibly the best understood for any plant species in Australia. Records show that this species range has contracted by 40% in area, and 26% latitudinally, through the loss of outlier and marginal populations since 1960. In addition, 22% of shrublands within the core distribution of *B. hookeriana* have been further lost over this period through clearing for farming, infrastructure, and mining. The area of shrublands declined at a rate of 0.3% per year in 1990–2001. At this rate, and a mean fire frequency of 14 years (equivalent to its mean generation time), *B. hookeriana* habitat is being lost at a rate of 4% per generation (Lamont et al., 2007). *B. hookeriana* may be absent from a further 10% of suitable habitat because recurrent fires are at intervals < 8 years that is too short for population survival (insufficient time for adequate seed production). Eighteen percent of the sandplain area lies within conservation/nature reserves, but a large, heavy mineral sand mine within one reserve reduces the effective conservation area to 16%. These reserves include 25% of the known populations and, as the two largest populations are among these, they represent 75% of individuals. Most of the remaining populations occur on vacant Crown land, and some in small fragments of vegetation in roadside reserves that tend to become heavily infested with exotic grasses over time. Population fragmentation also results in decreased seed set (the Allee effect).

The declining rainfall and possibly increasing fire frequency (at least in the short term) in this biome associated with climate change will, and is, exacerbating these trends, especially among serotinous, fire-killed species such as *B. hookeriana* (Enright et al., 2014). The heathlands are particularly vulnerable to the root pathogen, *Phytophthora cinnamomi*, especially the vegetation-defining Proteaceae, Fabaceae, Ericaceae, and *Xanthorrhoea*. This disease has devastated some stands in the southern sandplains and uplands of the Stirling Range. Concerted rehabilitation efforts following mining for heavy minerals has had considerable success at returning species richness but less so at restoring species composition and physiognomy. The restored vegetation is more vulnerable to fire as the resprouting species are less fire-tolerant. This is because they grow much faster and recruitment is lower as the silty surface soil inhibits root development (Herath and Lamont, 2009; Herath et al., 2009). Commercial flower and seed harvesting can have a severe effect on seed available for recruitment postfire as well as depleting the habitat of scarce nutrients. It has been noted that the greater growth and fecundity of plants along road verges, because of greater access to nutrients and water, may have conservation value. However these also act as pathways for the advancement of weeds, especially following fire and stray fertilizer from farms. Restricting harvesting to older stands, longer prescribed burning intervals and even hand-sowing have been recommended as improving the viability of targeted species. Research has not supported the expected adverse effects of spring rather than autumn burning on plant recruitment though possible effects on breeding animals has yet to be investigated. Encroachment by saline groundwater beneath coastal shrublands on highly porous sands as sea level rises and groundwater extraction escalates is a future threat.

Abstract

Mallee related maalok ecosystems are unique to southern Australia, having no direct analogue on other land masses. They straddle the interface between the Mediterranean-type and arid climate zones. The key environmental factors that shape mallee ecosystem functions and traits are severe summer water deficits, nutritional poverty, and fire regimes. These processes interact with herbivores, which are critical to regeneration of woody perennials in the postfire period. Approximately 30% of mallee ecosystems were converted to cropping and exotic pasture in the past 200 years. Future sustainability depends on a more representative protected area network, regulation of land use change, conservative livestock management, avoidance of short fire-return intervals, minimizing risks of recruitment failure, and approaches that build resilience to climate change.

Introduction

A distinctive suite of ecosystems stretches across almost the entire continental breadth of southern Australia, straddling the subhumid “Mediterranean-type” and semi-arid climate zones. This chapter focusses on mallee ecosystems in that bioclimatic region, which is dominated almost exclusively by eucalypts in sections *Bisectaria* and *Dumaria* largely on unconsolidated sandy substrates, excluding those of more humid regions on lithic substrates, and dominated by mallee eucalypts from other sections of the genus. The term “mallee” derives from indigenous languages in southeastern Australia, and refers to the distinctive growth form of dominant trees, characterized by multiple stems arising from a woody subterranean regenerative organ or lignotuber (Yates et al., 2017). Maalok differs from mallee vegetation in this respect because the dominant eucalypts are single-stemmed, nonlignotuberos and killed by fire, yet many of them have putative sister species with mallee growth forms (Gosper et al., 2019), and all belong to section *Bisectaria* of the genus *Eucalyptus*, as do most mallees. Mallee vegetation varies in height usually from 3 to 9 m tall, but exceptional sites support trees > 15 m tall (Parsons, 1994), and maalok reaches the upper part of this height range. Mallee tree densities vary from 1 to > 200 per hectare (Keith unpublished data), but densities in maalok may be much greater. Understorey vegetation varies physiognomically, structurally and compositionally in relation to regional climatic and edaphic gradients, fire regimes and biogeographic legacies.

Mallee ecosystems occupy a significant segment of a major regional climatic gradient extending from the southern coast of Australia, where mean annual rainfall may exceed 1000 mm with a prominent winter maximum, to the inland, where rainfall declines to 150 mm per annum, with aseasonal occurrence and very high interannual variability. Mallee ecosystems occur predominantly in a zone bounded by the 200 and 500 mm annual rainfall isohyets (Fig. 1), and are largely associated with unconsolidated aeolian sands. In subhumid temperate climates to the south, they transition to sclerophyll shrublands and eucalypt woodlands characterized by single-stemmed trees. With increasing aridity, they transition to desert shrublands dominated by chenopods or acacias, and hummock grasses. Mallee ecosystems are home to an endemic fauna including the mallee fowl (*Leipoa ocellata*) and mallee dragon (*Ctenophorus fordi*), as well as several fossorial mammals that went extinct, regionally or globally, in the modern era.

On a global scale, mallee ecosystems are biogeographically, climatically and functionally unique. Mediterranean-type climates in Europe, South Africa, Chile and California host sclerophyll shrubland and woodland systems that share a number of ecological

Fig. 1 Mapped distribution of mallee ecosystems in southern Australia (data from National Vegetation Information System, major vegetation subgroups version 5.1, <https://www.environment.gov.au/land/native-vegetation/national-vegetation-information-system/data-products#mvsg51>, downloaded 15/08/2019) in relation to 200 mm and 500 mm isohyets (data from Bureau of Meteorology, http://www.bom.gov.au/jsp/ncc/climate_averages/rainfall/index.jsp, downloaded 14/08/2019).

convergences with those in southern Australia (Rundel et al., 2016), but none of those systems are dominated by trees with subterranean regenerative organs. Similarly, chenopod shrublands are widespread in arid and semi-arid climates of the temperate Americas, Eurasia and southern Africa, as well as Australia. Mallee woodlands and shrublands, by contrast, seem to have no direct analogues in other parts of the world.

Mallee ecosystems appear to have mid Miocene origins (c. 15 million years ago) as the Australian continent underwent aridification. Diversification in *Bisectaria* and *Dumaria* clades accelerated from about 10 million years ago (Thornhill et al., 2019), apparently radiating from west to east as new aeolian substrates developed and became vegetated in the Murray-Darling depression (Yates et al., 2017). Other key components of mallee ecosystems, such as the hummock grass genus *Triodia*, have progenitors that arrived by long-distance dispersal from Asia in the mid Miocene, and spread from the south across the arid interior and into the tropics (Toon et al., 2015). Mallee ecosystems are core habitat for ancestral taxa of the genus, including *Triodia scariosa* and *Triodia irritans*.

This article examines current knowledge on the distribution and varied expressions of mallee ecosystems, the evolutionary biogeography of key taxa, gradients in major environmental drivers that shape their ecological features, and the traits of plants and animals that occupy these unique systems.

Distribution and Types of Mallee Ecosystems

Mallee ecosystems are distributed in a belt extending almost 3000 km, 400–600 km wide, from the Avon wheatbelt in southwestern Australia, through the south coastal hinterland, southern deserts and the Eyre and Yorke peninsulas to the Murray-Darling

depression and the eastern edge of the Cobar peneplain in central New South Wales (Fig. 1). The Nullarbor Plain, dominated by chenopod shrublands on heavy calcareous clay soils, imposes a major gap in the distribution, but mallee ecosystems occur semi-continuously both to its north and south.

Yates et al. (2017), building on a regional floristic analysis for mallee in the Murray-Darling region (Haslem et al., 2010), proposed five major types of mallee ecosystem based on contrasting understorey features and environmental associations (Fig. 2; Table 1).

Heathy Mallee

Heathy mallee marks the transition to sclerophyll shrublands in the more humid southern part of the distribution (Fig. 2), where annual rainfall exceeds 300 mm and has a winter maximum (Table 1). Soils are coarse-textured white sands and more siliceous than those of other mallee types or, more rarely, deeply weathered laterites of the southwest. The relative importance of reliable winter rains and siliceous sands in delimiting heathy mallee are difficult to evaluate because the latter are essentially replaced by calcareous sands as rainfall diminishes towards the continental interior. Heathy mallee typically occurs throughout the catenary sequence of these dune-swale landscapes. Lignotuberous mallee eucalypts dominate the vegetation, but there may be an appreciable component of nonlignotuberous trees, particularly *Callitris* and *Banksia*. The understorey flora includes conspicuous heathland plant families, such as Proteaceae, Ericaceae, Myrtaceae, Dilleniaceae, Rutaceae, and Rhamnaceae (Fig. 3A). Grasses and forbs are less conspicuous than sclerophyll shrubs and wiry graminoids. Recruitment of trees and shrubs is closely cued to fire. Western occurrences of heathy mallee in the Avon wheatbelt and south coast of Western Australia differ substantially in the species composition of both overstorey trees and understorey shrubs from eastern occurrences on the central-southern Eyre Peninsula and in the Ngarkat—Big Desert area to the south of the Murray River. Post-Miocene isolation is a likely cause of these differences, as the arid climate and heavy-textured soils of the Nullarbor Plain impose a dispersal barrier to many sclerophyll taxa.

Shrubby Mallee

Shrubby mallee occurs on calcareous sandplains receiving ~200–300 mm mean annual rainfall (up to 350 mm in some areas) through the entire east-west range of the mallee (Yates et al., 2017). It is commonly associated with extensive plains or swales, but is replaced by *Triodia* mallee on dunes and other areas of light-textured soils (Table 1). Lignotuberous mallee eucalypts are often the sole dominants and may exceed 10 m in height. Nonlignotuberous trees are typically absent but, amongst the eucalypts, other less frequent resprouting trees may include *Alectryon* and *Myoporum*. The most conspicuous shrubs are nonsclerophyll genera such as *Eremophila*, *Senna*, *Acacia*, *Olearia*, and *Maireana* (Fig. 3B), although a few sclerophyll shrubs may also be present (mainly *Acacia*, *Grevillea* or *Hakea*). Most of these species are widespread across Australia's arid zone. Shrubs tend to be long-lived (multiple decades) and most have subterranean regenerative organs, such as woody rhizomes or lignotubers. The non-woody component of the understorey is usually sparse, except after substantial rains, which tend to stimulate emergence and dominance of ephemeral forbs (mostly Asteraceae with Portulacaceae, Crassulaceae) and/or ephemeral grasses (mostly *Austrostipa*), depending on the contributions of autumn-winter and spring-summer rains (Robertson, 1988; Dwyer et al., 2015). Soils are generally calcareous red sandy loams, with greater silt and clay content in the subsoil, becoming very hard when dry. The soil surface is often consolidated by biological crusts comprising lichens, algae and bacteria, especially where surface water is slow to percolate or run-off after rains. These crusts have important roles in soil stability, moisture retention and nutrient cycling (Eldridge and Koen, 1998).

Fig. 2 Hypothesized relationships of different mallee ecosystems to regional climatic gradients and landscape edaphic gradients in southern Australia.

Table 1 Characteristic of mallee and maalok ecosystem types.

	<i>Heathy mallee</i>	<i>Shrubby mallee</i>	<i>Chenopod mallee</i>	<i>Triodia mallee</i>	<i>Maalok</i>
Mean annual rainfall	300–500 mm	200–350 mm	200–350 mm	150–350 mm	300–600 mm
Rainfall seasonality	Winter maximum	Aseasonal	Winter maximum—aseasonal	Aseasonal	Winter maximum
Substrate	Siliceous white sands	Red sandy loams sands	Red sandy loams sands	Deep red sands	Loams
Fire regime	Decadal to multidecadal scale summer canopy fires	Multidecadal to century scale summer canopy fires	Multidecadal to century scale summer canopy fires	Multidecadal to century scale summer canopy fires	Multidecadal to century scale summer canopy fires
Maximum tree height	< 10 m	> 10 m	> 10 m	< 10 m	> 10 m
Mallee trees	Dominant	Dominant	Dominant	Dominant	Absent

Hummock grasses	Uncommon	Absent	Absent	Common	Absent
Tussock grasses	Uncommon	Present	Common	Present	Very sparse
Biological soil crusts	Uncommon	Common	Common	Uncommon	Uncommon

Chenopod Mallee

Chenopod mallee dominates plains with subdued topography and red calcareous sandy loams, finer in texture than those supporting other mallee types (Table 1). It marks an edaphic transition to clay-dominated soils that support *Casuarina* (Belah) woodlands or treeless chenopod shrublands. Chenopod mallee occurs more extensively in the eastern and central parts of the mallee distribution than in the southwest (Fig. 1), mostly where rainfall averages 200–300 mm per annum (rarely up to 350 mm). Lignotuberous mallee eucalypts are the sole dominants or may be interspersed with rhizomatous *Casuarina* and *Alectryon*. The shrub stratum is characterized by subsucculent “chenopods” (family Amaranthaceae), *Maireana*, *Atriplex*, *Rhagodia*, *Sclerolaena*, and *Chenopodium* (Fig. 3C). Tussock grasses may be abundant, depending on rainfall and herbivore activity, sometimes more conspicuous than chenopod shrubs, while communities of ephemeral forbs vary interannually depending on autumn–winter rains. As for shrubby mallee, soil crusts of lichens, mosses, algae and bacteria play a prominent role in ecosystem processes. Perennial plant recruitment, at least in the understorey, appears to be regulated primarily by rainfall variability and herbivore activity. While grass-dominated areas of chenopod mallee are fire-prone, chenopod-dominated fuels are likely to be less flammable than those of other mallee systems.

Triodia Mallee

Triodia mallee extends from the Cobar penplain to the Avon wheatbelt across extensive red calcareous sand dune landscapes. It marks the dry extremity of the mallee climatic gradient (Fig. 2), where mean annual rainfall diminishes to 150 mm towards the interior, and rainfall patterns are aseasonal and highly variable between years (Table 1). Surface-soils are unconsolidated sands, with loamy subsoils occurring one to several metres below the surface. Mallee eucalypts dominate the tree canopy, occasionally with nonlignotuberous species (*Callitris*, *Codonocarpus*). Shrubs are spatially and temporally variable in density, with nonsclerophyll foliage and recruitment cued to fire. Common genera include *Beyeria*, *Olearia*, *Acacia*, *Eremophila*, *Halgania*, and *Duboisia*, many of which are short-lived (< 20 years), deep-rooted with persistent soil seedbanks. Long-lived hummock grasses (*Triodia*) are distinctive features of the ground layer (Fig. 3D), but there are few other perennial nonwoody plants in the system. Ephemeral grasses (*Austrostipa*) and forbs (Asteraceae, Portulacaceae, Crassulaceae) may be common after rains and may be critical to the spread of fires (Noble and Vines, 1993), which occur at multidecadal intervals, and become less frequent with aridity.

Maalok

Maalok is confined to southwestern Australia extending from the semi-arid zone to wetter climates than mallee vegetation (300–600 mm per annum), although they may occupy depressions between sand dunes or very weathered lateritic rocky sites, juxtaposed with heathy mallee on coarser-textured white sands (Beard, 2015; Yates et al., 2017). As noted earlier, the dominant eucalypts are single-stemmed, nonlignotuberous and killed by fire (Table 1). Maalok eucalypts may grow in high densities (Fig. 3E), and hence

Fig. 3 (A) Healthy mallee in with *Eucalyptus dumosa*, sclerophyll shrubs of *Leptospermum*, *Melaleuca lanceolata*, *Hibbertia* and scattered *Triodia irritans* and *Amphipogon caricinus* in the ground layer. Note bleached white sand heaped into a nesting mound by mallee fowl. Hambidge Wilderness Protection Area (Eyre Peninsula). (B) Shrubby mallee in a dune swale with *Eucalyptus socialis* (center) and *Eucalyptus gracilis* (background, left), a prominent mostly nonsclerophyll shrub layer of *Senna petiolaris*, *Eremophila glabra*, *Dodonaea angustifolia*, *Acacia burkittii*, and *Acacia colletioides* and a soil crust of alga and mosses interspersed with depositional sands. Tarawi Nature Reserve, Murray-Darling depression. (C) Chenopod mallee on a flat sand plain with *Eucalyptus oleosa* (commonly a dominant tree species of chenopod mallee), *Maireana sedifolia* (pearl bluebush, most abundant shrub), *Olearia muelleri* (a daisy bush with bright green foliage) and an algal soil crust. Tarawi Nature Reserve, Murray-Darling depression. (D) Triodia mallee on a red dune crest with *Eucalyptus socialis* (foreground) with *Eucalyptus costata* (background, a characteristic species of Triodia mallee) with scattered shrubs of *Beyeria opaca*, *Acacia ligulata*, *A. rigens*, *Eremophila glabra* and *Olearia subspicata* and the hummock grass, *Triodia scariosa* (right) with loose sand and leaf litter on the surface. Tarawi Nature Reserve, Murray-Darling depression. (E) Maalok with a high density of single-stemmed nonlignotuberous *Eucalyptus platypus* and a sparse understorey with high cover of leaf litter. Sclerophyll shrubs are likely represented in the soil seed bank. Ravensthorpe Range, Southern Avon wheatbelt, Western Australia. (F) Postfire regeneration of Triodia mallee showing fire-killed prefire mallee stems and new postfire stems emerging from lignotubers in *Eucalyptus dumosa* (left). Other regenerating plants include shrub seedlings and resprouting Triodia hummocks. Dangdali Conservation Park, Reserve, Murray-Darling depression, 2 years after a fire in 2010. their sclerophyll shrub understories may be quite sparse. Common shrub families include Myrtaceae, Fabaceae, Rutaceae, and Proteaceae. Grasses and forbs are not major components of maalok vegetation. The characteristically sparse ground fuels and lack of ladder fuels limit the spread of fires through mature stands, which may experience fire-return intervals exceeding 100 years. Fires nonetheless play profound roles in tree regeneration, vegetation structure and composition of maalok vegetation (Gosper et al., 2018).

Key Drivers of Mallee Distribution and Ecology

Summer water deficit, nutritional poverty and fire regimes are key drivers of mallee ecosystem dynamics and have a key role in shaping ecosystem traits and functions. Herbivores have important roles in trophic functions and plant regeneration in some mallee systems (chenopod mallee, *Triodia mallee*), less so in others (heathy mallee, maalok).

Summer Water Deficit

Mallee ecosystems experience a severe summer water deficit due to low annual rainfall, a winter-maximum/summer-minimum seasonal pattern of occurrence, and extreme summer temperatures which promote high rates of evapotranspiration (Keith and Tozer, 2017). Summer water deficits are exacerbated by low soil moisture retention associated with sandy texture.

Summer water deficit varies markedly between years due to interannual variation in weather driven by El Niño—Southern Oscillation and Indian Ocean Dipole climatic cycles (Meyers et al., 2007), and as well as summer monsoonal weather systems that penetrate occasionally from the tropics to the southern inland in some years. The effects of water deficit diminish with depth below the surface, and subsoils may retain surprisingly higher levels of moisture and undergo markedly less variation than those near the surface (Fig. 4). These effects vary with topography and soil texture (Fig. 4). This has implications for water acquisition in shallow-rooted plants, including seedlings of deep-rooted species.

Summer water deficits vary across regional climatic gradients, with rainfall declining towards the inland (Figs. 1 and 2), and through local catenary and edaphic gradients. Water run-on and infiltration in local depressions can greatly influence moisture accumulation, while soil texture influences water retention. Water deficits are expected to be most severe in *Triodia mallee* due to its position at the arid end of the mallee climatic gradient and its light-textured soils (Fig. 4). Heathy mallee occurs in wetter climates, but their lighter-textured soils may experience greater moisture loss due to both percolation and capillary rise. The higher

Fig. 4 Soil moisture traces at two depths (10 cm, 80 cm) for a dune crest supporting *Triodia mallee* and a swale supporting Shrubby mallee in Tarawi Nature Reserve. Moisture content at 10 cm depth is critical to germination, growth and survival of perennial seedlings and ephemeral plants. Moisture at 80 cm depth and below is accessible to established perennial shrubs and trees. Swale soils have smaller particle sizes than crest soils, especially in the subsoil. Swale soils, with rare exceptions, have higher moisture content than crest soils throughout the soil profile. Swale soils exhibit higher moisture variability than crest soils at the surface and lower moisture variability in the subsoil.

silt and clay content of subsoils beneath chenopod mallee, shrubby mallee and maalok may enable greater water retention, but it is not known whether clay content is high enough to cause reverse-texture effects (Noy-Meir, 1973).

Diverse traits associated with drought resistance and water conservation are evident in plants and animals that inhabit mallee ecosystems. Many plants exhibit reduced leaf forms including phyllodes (*Acacia*, *Senna*), cladodes (*Exocarpos*, *Logania*) and narrow or needle leaf shapes (*Acacia*, *Hakea*, *Triodia*). These, together with thick waxy cuticles, leaf vestiture and stomatal regulation and invagination reduce transpirational water loss through leaves. *Triodia* and some chenopods also have C_4 photosynthetic pathways, enabling them to fix CO_2 during night time and absorb light through photosynthesis during the day while stomatal pores are closed. Many vertebrates have analogous physiological traits enabling uptake of water from plant forage with reduced dependence of standing water, which becomes rare in mallee landscapes during summer. Behavioral traits also enable avoidance of high temperatures and reduce exposure to desiccation, including nocturnal activity cycles, common in mammals with small and medium body sizes, and resting in shady refuges or burrows. Macropods, emus and many other birds are able to move large distances to access available water. Many perennial plants have deep root architecture, enabling them to access reliable sources of moisture in subsoils. Roots of mallee eucalypts, for example, have been found at depths exceeding 25 m (Parsons, 1994). This is coupled either with rapid early growth enabling young winter germinants to access deep moisture before the first summer, or very long-lived adult life stages, which reduce the population-level impact of successive recruitment failures and exploit rare years when soil moisture remains at high levels through the summer. Conversely, many plants and animals (notably insects and some small mammals) have ephemeral life cycles, enabling them to complete their life cycles during periods of high moisture availability and persist through dry phases as dormant propagules (e.g., soil seed banks).

Although all mallee ecosystems routinely experience summer water deficits, large interannual variations influence both impacts on biota and opportunities for regeneration. Extreme mortality responses to century-scale drought events have been shown to leave transformative legacies on ecosystem identity and function across arid and semi-arid Australia, including mallee ecosystems (Godfree et al., 2019). Heat shock events, where afternoon summer temperatures exceed $50^\circ C$, may amplify the impacts of prolonged droughts, and both are expected to occur more frequently under future climates. Conversely, exceptionally large rainfall events may be critical to recharging resources, fuelling boom-bust productivity and trophic webs, and to long-term persistence of long-lived perennial plants, which rely on infrequent recruitment episodes to compensate attrition of established individuals (Morton et al., 2011; Wardle et al., 2013).

Nutrient Poverty

Mallee ecosystems have low stocks of phosphorus and nitrogen. Mapping by CSIRO suggests that surface soils contain 0.01–0.02% total phosphorus and 0.03–0.05% total nitrogen by weight (Keith and Tozer, 2017). Calcium dominates the cation exchange complex of most mallee soils. Vegetation accounts for 8 and 7 $kg \cdot ha^{-1}$ of phosphorus above- and below-ground, respectively, and 140 and 100 $kg \cdot ha^{-1}$ of nitrogen above- and below-ground, respectively (Burrows, 1976 cited in Parsons, 1994).

In general, mallee soils with greater clay content have higher nutrient levels than those with high sand content. In dune landscapes, soil phosphorus and cation exchange capacity may increase by a factor of 4 or 5 from the dune crest to the swale (Unkovich, 2014), indicating the substantial difference in nutrient availability between *Triodia* mallee on dunes and shrubby mallee in swales. The nutritional contrast between siliceous sands of heathy mallee and the loamy sands of chenopod mallee is likely to be even greater (Fig. 2).

Differences in nutrient status among mallee vegetation types are most evident in leaf traits of shrubs. The sclerophyll morphology of shrub leaves in heathy mallee and maalok likely reflect low levels of soil phosphorus, which in combination with abundant light and CO_2 and seasonally available moisture, result in production of excess carbohydrate directed into production of cellulose and lignin, rather than photosynthetic tissues (Orians and Milewski, 2007). Sclerophyll is virtually absent from shrubs in chenopod mallee, and less pervasively represented in the shrub floras of shrubby and *Triodia* mallee. The greater abundance and diversity of grasses in these latter vegetation types relative to heathy mallee and maalok may also reflect nutritional differences.

Fire Regimes

Patterns in fire occurrence

All mallee vegetation types and maalok are fire-prone. Murphy et al. (2013) predicted that mean fire return intervals for mallee vegetation varied from 20 to 100 years and fireline intensity varied from 1000 to 5000 $kW \cdot m^{-1}$, with extreme values up to 50,000 $kW \cdot m^{-1}$. Empirical estimates for heathy mallee in southwestern Australia reviewed by Gosper et al. (2016) were broadly similar, although typical intensities were slightly higher and fires occurred in summer-autumn, rather than spring-summer.

Models extrapolated from satellite image time series in the Murray-Darling depression estimate that time since last fire varies up to 110 years, with the oldest mallee distributed mainly in the northwest of that region where mean annual rainfall is lowest and landscapes are dominated by shrubby and *Triodia* mallee. Higher rainfall areas in the south, dominated by heathy mallee, generally had fires within the last 3 years.

Gibson et al. (2015) fitted failure time models to mapped fire history (1930s—present) to examine the influence of environmental covariables on fire regimes in the Murray-Darling Depression. They found that higher rainfall was consistently associated with shorter fire intervals, and that the probability of burning at a point was independent of time since fire, except in shrub-

dominated mallee communities at high rainfall (i.e., heathy mallee). They also found that higher-fertility sands were associated with shorter fire intervals in grass-dominated communities (i.e., chenopod mallee), whereas lower-fertility sands were associated with shorter fire intervals in shrub-dominated communities (heathy mallee cf. *Triodia* mallee).

Noble and Vines (1993) suggested that ephemeral fuels (primarily tussock grasses and forbs) promoted by antecedent rainfall were critical to extensive spread of fire, since these connected patches of eucalypt leaf litter and *Triodia*, fuel elements that otherwise remained discontinuous and unable to sustain fire spread except under strong winds. The limitations on fire spread in the absence of ephemeral fuels, irrespective of the age of perennial fuels, may explain Gibson et al. (2015) failure to detect a relationship between the probability of burning and time since fire in semi-arid mallee.

Plant traits and fire responses

The mallee flora is equipped with a number of morphological and life-history traits enabling persistence under a regime of canopy fires occurring at multidecadal frequencies during summer-autumn seasons. Morphological traits include subterranean woody regenerative organs, thick bark, canopy seedbanks and physical or physiological seed dormancy with fire-related germination cues (Gosper et al., 2012; Yates et al., 2017). Plant life histories vary from long-lived stress tolerators to fecund ruderals, with fires influencing survival, growth and reproduction in the former, and reproduction in the latter.

All mallee eucalypts have similar fire response traits (Fig. 3F). Their aerial stems have thin bark and are killed even by low intensity fires. New stems resprout from subterranean lignotubers, increasing in girth and height, and reducing in number with time since fire. Survival rates of established plants are typically high (>95%), but are much reduced under successive fires in spring (Noble and Diggle, 2013). Seeds are retained in woody fruits (serotinous seed banks) where they are insulated from the lethal heat during fire and subsequently released onto the ash bed. Seed bank turnover rates are high (c. 2 years) and fruit production is variable among years, so seed banks may be small or absent in some years (Keith and Tozer unpublished data). Seedling recruitment occurs almost exclusively after fire and is highly variable between fires. Recruitment failure may result from either small pre-fire seed banks, insufficient soil moisture to initiate germination, or high seedling mortality due to desiccation. As standing plants may live for several centuries (Wellington et al., 1979), even relatively rare recruitment events are sufficient to maintain stable populations. Maturation rates are slow. Although lignotuber development commences within the first year, it may take two or more decades for the majority of a cohort to develop sufficiently to survive their first fire. Flowering generally also commences within the third decade of life, although vigorously growing seedlings of *Eucalyptus costata* may produce their first seed crop within one decade.

With the exception of *Callitris*, fire-killed trees are uncommon in mallee, but dominate maalok (Table 1). Their growth and maturation rates are faster than those of mallee eucalypts, fecundity rates are greater and their serotinous seed banks persist for longer. Recruitment is closely associated with fires, which may result in high densities of seedlings. Nonetheless, population persistence is highly sensitive to short fire return intervals relative to maturation times and reestablishment of seed banks, which are entirely exhausted by a single fire (Bradstock and Cohn, 2002). They are also sensitive to recruitment failure associated with high interannual rainfall variability.

Fire-killed shrubs are especially prominent in *Triodia* mallee and may also be common in heathy mallee (Table 1). Unlike eucalypts and *Callitris*, most accumulate persistent soil seed banks that remain physically or physiologically dormant until fire-related germination cues (usually heat shock or smoke-associated chemicals) coincide with suitable temperature and moisture conditions. Seed bank longevity is poorly studied but anecdotal observations suggest it may extend to many decades or beyond a century. Standing plant longevity is shorter, with senescence occurring at 10–30 years of age for a range of species.

Resprouting shrubs are most common in shrubby mallee and heathy mallee (Table 1). While aerial stems are killed, they resprout from lignotubers or woody rhizomes. Their standing plants are slower-growing and longer-lived than fire-killed species, and they tend to be less fecund and may be expected to have smaller and less persistent soil seed banks due to reduced selection pressures on postfire recruitment. *Triodia*, although C₄ grasses, resemble resprouting shrubs in growth form and life history. Individuals form wiry, spiny hummocks and persist for more than a century, resprout from clustered underground rhizomes and recruit after fire from ostensibly short-lived soil seed banks. Interestingly, some populations are comprised entirely of fire-killed plants.

Unlike other shrub groups, seedling establishment occurs semi-continuously throughout the fire cycle in chenopod shrubs (*Maireana*, *Sclerolaena*, *Chenopodium*, *Atriplex*) and a few other species. When dominant in mallee understories (as in chenopod mallee, Table 1), they are less flammable than sclerophyll shrubs and *Triodia*, but standing plants are killed when burnt and population persistence relies on regeneration from seeds.

Ephemeral forbs and grasses are significant components of shrubby mallee and *Triodia* mallee. The forbs germinate and grow in the cool seasons of wet years, producing a seed crop before the onset of the fire season, and senescing in the warmer months. As noted above, emergence varies greatly between years with rainfall, but the magnitude of recruitment is generally enhanced by fire (Parsons, 1994). Ephemeral C₃ grasses (primarily *Austrostipa*) have similar life histories, but their phenology differs, with emergence occurring in spring, maximum growth and reproduction occurring in late spring-summer. Senescence and curing in mid-late summer contributes significantly to available fuels in years of high abundance (Noble and Vines, 1993).

At the community level, there is strong evidence of trends in plant species richness and composition with time since fire in *Triodia* mallee as standing plants of ephemerals and short-lived fire-killed shrubs decline in abundance and return to the soil seed bank (Parsons, 1994; Yates et al., 2017). Similar trends are less evident, or play out more slowly in heathy mallee (Gosper et al., 2012), as such life histories are not major components of those communities and standing plants are longer lived.

Pausas and Bradstock (2007) suggested that the relative proportions of fire-killed and resprouting woody plant species were related to a fire-productivity gradient in southeastern Australian mallee. They found that the proportion of fire-killed species

increased as mean annual rainfall and fire frequency declined from south to north. Subsequent work by Gibson et al. (2015) suggests that these relationships are more complex, however, as substrates interact with rainfall and fire regime gradients. In the low-rainfall regions, for example, most of the fire-killed shrubs are confined to light-textured soils on dunes (*Triodia mallee*), whereas resprouters dominate heavier-textured sandy loams in the swales (shrubby mallee).

Conservation

Major threats to mallee and maalok ecosystems include habitat loss and fragmentation related to land use intensification, invasive species, degradation of soils associated with cropping and livestock grazing, changes in fire regimes and climate change.

Mapping included in the National Vegetation Information System (Major Vegetation Subgroups version 5.1, <https://www.environment.gov.au/land/native-vegetation/national-vegetation-information-system/data-products#mvsg51>), estimates the pre-European extent of mallee ecosystems to be 400,000 km², of which about 30% has been cleared, primarily for dryland cropping in the wheatbelts of Victoria, South Australia and Western Australia. Earlier estimates suggest a smaller extent, but similar proportion cleared (DEWR, 2007). The impacts of these losses have fallen disproportionately in high rainfall areas (Yates et al., 2017) and on chenopod mallee, which has the most favorable soils for crop production. It is likely that clearing has eliminated much more than half of chenopod mallee distribution. Losses of shrubby and heathy mallee have also been appreciable, while *Triodia mallee* and maalok have been less affected, as their climate and soils are less suitable for agriculture.

Clearing has left ongoing legacies related to habitat fragmentation, which limits the viability of isolated populations of plants and animals in remnant patches (Luck et al., 1999a, 1999b), promotes incursions of invasive species, disrupts native animal movement and herbivory, and changes patterns of fire ignition and spread. Large protected areas have been established to limit the impacts of clearing and fragmentation, but their coverage is biased towards mallee vegetation types that are least at risk from clearing, notably *Triodia mallee*.

Invasive species have had major historical and ongoing impacts on mallee ecosystems. Feral foxes and cats are predators of a diverse range of native mammals, birds, reptiles, and insects. They are strongly implicated in regional and global extinctions of medium-sized mammals (Johnson and Isaac, 2009), including fossorial species that had major roles as ecosystem engineers in nutrient and carbon cycling, soil structure and plant recruitment (Eldridge and James, 2009).

Feral rabbits and goats, together with overgrazing by domestic livestock, have direct impacts on woody and nonwoody vegetation (Cohn and Bradstock, 2000), reducing vegetation cover and structural complexity, with implications for exposure of native animals to feral predators. Impacts on regeneration of native shrubs and trees are particularly severe in some areas. Domestic and feral herbivores also contribute to soil degradation through disruption of biological soil crusts, compaction and by mobilizing surface soils and increasing their exposure to erosive winds (Mallen-Cooper et al., 2018). Erosion and redeposition of soil several metres deep has been documented in a number of areas, for example, through burial of fence lines (Unkovich, 2014).

Landscape-scale and targeted control programs aim to abate these threats posed by invasive species. These include release of biological control agents for rabbits, targeted baiting, culling and habitat management programs directed at foxes, cats and rabbits, construction of large enclosures enabling elimination of feral animals within, as well as active restoration of soils and woody vegetation. Ongoing control of feral animals will be crucial to maintaining function and diversity of mallee ecosystems, as will implementation of conservative stocking regimes in pastoral areas, with responsive reduction of livestock densities early in drought cycles. Reestablishment and maintenance of perennial shrub strata are critical to sustainability of these systems.

Changes in fire regimes threaten mallee and maalok ecosystems through at least three different mechanisms. Firstly, increases in fire frequency may erode diversity by interrupting seed bank reaccumulation in fire-killed plants, especially those with long maturation times (Bradstock and Cohn, 2002; Gosper et al., 2013, 2018). Frequent fires also maintain a greater portion of the landscape in young age classes, unsuitable for animal species dependent on old mallee habitat features (Kelly et al., 2011). Secondly, changes in the timing of fires may increase the probability of recruitment failure associated with extreme postfire water deficit. This could occur through increased fire occurrence in autumn (Noble and Diggle, 2013) or increased fire frequency at any time of year, which increases the probability of drought conditions during the postfire period. Thirdly, fires may enhance foraging efficiency of feral herbivores and predators, increasing mortality of regenerating perennial plants and native vertebrates, respectively. More work is needed to identify fire regimes associated with these effects, but fire frequency and spatial pattern are expected to be important.

Fuel reduction burning has been central to fire management in the mallee to reduce the likelihood of extensive unplanned fires (Yates et al., 2017). These are sometimes applied in spring when there are significant risks to mallee biota. The poor relationship between the probability of burning and fuel age (Gibson et al., 2015), together with the potential for rapid accumulation of ephemeral fuels in wet years (Noble and Vines, 1993), and continued occurrence of large fires driven by extreme weather, raises questions about the effectiveness of extensive fuel reduction as a core management strategy in semi-arid climates. Future fire management strategies need to address the mechanisms underpinning risks to mallee ecosystems, given the developing understanding of life-history responses of mallee biota, with flexibility to adjust management to current ecosystem states (Yates et al., 2017).

Projections of future climate suggest increases in mean temperature and frequency of days exceeding 40 °C, declines in rainfall particularly in winter, and increased frequency of extreme fire weather, all consistent with a southward shift in Australia's arid and Mediterranean climate zones (IPCC, 2014). The implications of such changes for mallee and maalok ecosystems are diverse. Reduced reliability of rainfall is likely to result in reduced cropping yields (Anwar et al., 2007), with more prolonged periods of exposed soils and associated erosion, impacting remnant mallee vegetation in cropping landscapes. Ultimately, dryland cropping

may become economically and ecologically unviable in these areas, prompting a shift to grazing enterprises and some opportunities for reconstructing mallee ecosystems. Technological innovations, such as drought-resistant crop strains, may prolong this transition. Declining rainfall is also impacting pastoral land uses, with economic pressures driving lags in destocking during drought events, in turn driving further erosion of perennial plant cover and resilience of the system to drought. Increasing aridity, together with legacies of past soil degradation have also driven a shift from sheep or cattle farming to harvest of wild goats, which have lower water requirements, lower investment and maintenance requirements and greater impact on perennial vegetation due to their broader diet.

In more natural areas, climate change may be expected to drive increased frequencies of major plant and animal mortality events associated with heat waves and increased frequencies of plant recruitment failure. Over long time scales, these processes may drive transition of *Triodia* mallee to desert shrubland in some areas and more subtle transitions in others. Changes in fire regimes are difficult to predict and depend on human ignition patterns. However, maalok and some heathy mallee systems may be under pressure from 'interval squeeze' if increased frequencies of extreme fire weather are reflected in fire frequencies that promote declines in fire-killed plants that rely on seed-bank reaccumulation between successive fires for population persistence. Drier parts of mallee distribution, even if they experience reduced fire frequency as a consequence of rainfall-related declines in fuels, are likely to be subject to increased risks of recruitment failure related to postfire droughts.

Aside from mitigation actions to reduce global warming, sustaining mallee ecosystems under future climates will depend critically on maintaining and building resilience by reducing pressures related to clearing and fragmentation, overpopulation of domestic, feral and native herbivores, soil degradation and fire regimes.

Abstract

This paper is a status assessment of Hawai'i's dry grasslands and shrublands, including its pre-human condition; current status, stressors, and conservation efforts; and future viability. Dry grasslands and shrublands in Hawai'i, including dry cliffs, generally have a hot and dry climate with relatively low annual rainfall and are characterized by being located in lowland, montane-subalpine, or alpine zones. These zones are differentiated by elevation and climate, which primarily dictate which species can exist in them (Gagne and Cuddihy, 1999). Prior to human arrival, dry grasslands and shrublands occurred on all of the main Hawaiian islands as well as Nihoa and Mokumanamana (Necker) in the Northwestern Hawaiian islands. Currently, they are still found on the same islands. However, the extent of the native species-dominated parts of this ecotype has greatly reduced in size. In addition to native sub-ecotypes, introductions of nonnative species resulted in two new sub-ecotypes referred to as introduced dry grasslands and introduced dry shrublands, which have become widespread. Our assessment of dry grassland and shrubland viability, defined as the likelihood of persistence over the long term, is based on

the concepts of resiliency, redundancy, and representation. The main stressors to dry grasslands and shrublands have been identified as invasive ungulates, invasive plants, invasive herbivores, fire, drought, natural disasters, climate change, and human development. Conservation efforts help to protect and restore native areas of dry grasslands and shrublands, and largely depend upon the actions of Federal, State, private, and multi-agency partnerships. The level of these conservation efforts and their impact on stressors determines the future viability of Hawai'i's dry grasslands and shrublands.

Introduction

The Hawaiian archipelago is the most isolated landmass in the world, consisting of some 132 islands, including 8 larger islands, and numerous smaller islands, islets, atolls, reefs, and shoals. The entire archipelago stretches 1603 miles (mi) (2580 kilometers (km)) on a southeast-northwest line across the middle of the Pacific Ocean. More than 99% of the land area is concentrated within eight larger, younger islands on the southeastern end of the chain (Wagner et al., 1999). These are referred to as the main Hawaiian islands and are named as follows: island of Hawai'i, Maui, Moloka'i, Lāna'i, Kaho'olawe, O'ahu, Kaua'i, Ni'ihau. The remainder of the archipelago to the northwest is made up of a much older and smaller collection of islands and atolls known as the Northwestern Hawaiian islands (NWHI). The NWHI consists of Nihoa, Mokumanamana (Necker), 'Ōnūnui (Gardner Pinnacles), Lalo (French Frigate Shoals), Kamole (Laysan), Kapou (Lisianski), Manawai (Pearl and Hermes), Kuaihelani (Midway), and Hōlanikū (Kure). The existence of a diversity in climate, geography, hydrology, and other environmental factors has resulted in a variety of biomes (forests, grasslands, shrublands, wetlands, etc.) in the Hawaiian islands. This paper provides an overview of Hawai'i's dry grasslands and shrublands and describes the factors that have impacted them over time and that will into the future.

Description

Defining Dry Grassland and Shrubland Characteristics

A grassland is defined as a plant community that has greater than 40% cover in grasses (Gagne and Cuddihy, 1999). Similarly, a shrubland is defined as a plant community that has greater than 40% cover in shrubs (woody plants 1–10 feet (ft) (1–3 meters (m)) tall and often with multiple stems) (Gagne and Cuddihy, 1999). Dry grasslands and shrublands occur primarily on the leeward sides of the islands in hot, dry climates with relatively low annual rainfall and are found in lowland, montane-subalpine, or alpine zones. These zones are differentiated by elevation and climate, which primarily dictate which species can exist in them (Gagne and Cuddihy, 1999), and are described further in the Pre-human Condition and Current Condition sections below. Dry grassland and shrubland occurs on all of the main Hawaiian islands from 50 to 11,100 ft. (15 to 3400 m) elevation (LANDFIRE, 2016), with annual rainfall ranging between 4 and 69 inches (in) (10 and 175 centimeters (cm)) (Gagne and Cuddihy, 1999). This ecotype also includes dry cliffs, which are defined by their occurrence in areas with steep slopes (greater than 65 degrees) that are away from the direct influence of the shoreline.

Geology

Substrates are highly variable throughout this ecotype. In the lowlands, dry grasslands often occur on thin soils and old lava flows while dry shrublands vary from silty loams to relatively unweathered pāhoehoe (Gagne and Cuddihy, 1999). Montane dry grasslands have either a sandy loam soil or less developed cindery soil (Gagne and Cuddihy, 1999). Montane-subalpine dry shrublands occur on sandy-loamy soils derived from volcanic ash or sand, or weathered lava (Gagne and Cuddihy, 1999). Alpine dry shrublands are well-drained and gravelly, and are derived from cinder and ash (LANDFIRE, 2016). Dry cliff substrate includes sandy loam soils derived from cinder, volcanic ash, and weathered basaltic lava with little soil development (LANDFIRE, 2016).

Vegetation structure and composition

Dry grasslands and shrublands vary in vegetation structure and composition. The dry shrubland ranges from an open to dense shrub layer up to 2 m in height in lower elevational zones (LANDFIRE, 2016), to sparse and almost non-existent vegetation in the higher elevational alpine shrubland (Gagne and Cuddihy, 1999). In the alpine shrubland, only plant communities that are morphologically and/or physiologically adapted to extreme conditions can survive (Gagne and Cuddihy, 1999). Dry grasslands range from a moderate to dense layer of grass up to 1 m tall (LANDFIRE, 2016). Dry cliffs generally have sparse vegetation, composed of an open shrub or herbaceous layer that's restricted to ledges or less steep slopes (LANDFIRE, 2016).

Other biotic components

Dry grasslands and shrublands provide habitat to many birds and invertebrate species, which have a functional role in the ecological processes of this habitat. Birds, along with wind, are integral in the dispersal and pollination of plant species in dry grasslands and shrublands. Lowland dry grasslands and shrublands may support native birds such as large flightless geese and ducks (family Anatidae) and thrushes (family Turdidae) (Chimera and Drake, 2011). Native invertebrates also play an important role in pollinating plant species, particularly in dry shrublands (Magnacca, 2007).

Dry cliffs provide nesting habitat for some species of seabirds (HDLNR, 2015). Seabirds provide important nutrients from the marine environment such as nitrogen and phosphorus to the substrate, which are essential to vegetation recovery and health (Fukami et al., 2006; VanderWerf et al., 2014).

Physical/life history components

Natural recruitment in dry grasslands and shrublands is driven by numerous factors including disturbance from fires, drought, hurricanes, volcanism, storms, pathogens, diseases, and invertebrate pests. It can also be influenced by rainfall, light, and nutrient availability.

Water availability in dry grasslands and shrublands is dependent on rainfall and elevation. In the lowlands, rainfall is mostly restricted to winter months, while summers are hot and dry (Gagne and Cuddihy, 1999). Montane-subalpine areas have a seasonal climate with drought conditions during the summer months (May to October) and rainfall mostly in the winter months (November to March) (Gagne and Cuddihy, 1999). Alpine dry shrublands have an extremely dry and cold climate, with frequent frost that occurs even in the summer months. Rainfall in the dry, leeward sides of the Hawaiian islands most commonly occur as a result of frontal storm systems that are distributed over a large area and are broad; and convective storm cells, which are localized to a particular area and are small (Cordell and Sandquist, 2008). The sporadic appearance of rainfall during drought periods from convective storms, although small and for the most part do not account substantially to annual primary productivity in dry grasslands and shrublands, are important in the maintenance and existence of woody plants present in dry shrublands (Cordell and Sandquist, 2008).

Fire can act as a primary driver for change in dry grasslands and shrublands, and reset the successional clock by removing a substantial amount of plant biomass and significantly reducing the presence of several plant species. Some seeds will survive and be able to germinate following the fire, however, others rely on dispersal from other sources such as the wind or animals. Most native species in Hawai'i are not specifically fire adapted (Smith and Tunison, 1992), while invasive grasses (e.g., fountain grass) can be highly fire-adapted and regenerate quickly after fire (Fujioka and Fujii 1980 in Cuddihy and Stone, 1990; D'Antonio and Vitousek, 1992).

System Viability

The viability of dry grasslands and shrublands is defined as the likelihood of persistence over the long term. This depends on maintaining multiple and distributed populations (redundancy) of sufficient quality and size (resiliency), with species richness and genetic range (representation) to survive across their ecological environment over time.

Adequate distribution across the landscape contributes to its ability to perpetuate after a catastrophic event in one area by having a redundant population in another area. Regeneration of vegetation starts through succession and natural recruitment influenced by dispersal, rainfall, light, and nutrient availability. Dispersal mechanisms such as animals or wind, along with the optimal water availability mentioned above allow dry grasslands and shrublands to persist before and regenerate after catastrophic events.

The quality and size of dry grasslands and shrublands contributes to its resiliency in the face of stochastic events. Typical stochastic events for this ecotype include flooding or minor fires. Factors that affect the quality, and therefore the resiliency, of dry grasslands and shrublands include the pre-disturbance biodiversity and vegetation type (i.e., native or nonnative dominated). Dry grassland and shrubland stands that are composed of a higher proportion of native species have a greater likelihood to recover to predominantly native species cover whereas stands that were dominated by non-native species typically recover to non-native species dominance post-disturbance. Larger patch sizes of dry grasslands and shrublands typically harbor a larger number and greater abundance of native plant species and are therefore more resilient.

Diversity (e.g., geographic, genetic, and species diversity) within and among locations of dry grasslands and shrublands is necessary to enhance its ability to adapt to change. Dry grasslands and shrublands are best represented when there is geographic and genetic diversity across the range. Typical representation considerations include biodiversity and presence across a wide range of the islands; both on windward and leeward sides, and from lowland to alpine elevations.

Pre-Human Condition**Dry Grassland and Shrubland Sub-Types**

Before the arrival of humans, Hawai'i's dry grasslands and shrublands were represented by six sub-types: dry cliff, lowland dry grassland, lowland dry shrubland, montane-subalpine dry grassland, montane-subalpine dry shrubland, and alpine dry shrubland (Table 1).

Physical/life history components

The historical fire regime in Hawai'i was characterized by infrequent, low severity fires, as few natural ignition sources existed (Cuddihy and Stone, 1990; Smith and Tunison, 1992). It is believed that prior to human colonization, fuel was sparse in dry plant communities and most native vegetation had a low flammability (Cuddihy and Stone, 1990), Smith and Tunison, 1992). *Heteropogon contortus* (Pili grass), however, was adapted to survive fires and may have benefited from burnings (Cuddihy and Stone, 1990). Vogl (1969, in Cuddihy and Stone, 1990) proposed that naturally occurring fires may have been important in the development of some of the original Hawaiian flora adding to the species richness of ecotypes including dry grasslands and shrublands. As naturally occurring fires destroyed many woody species in forests, species in dry grasslands such as pili could persist.

Table 1 Pre-human dry grassland and shrubland sub-types.

Sub-type	Precipitation (cm) (Gagne and Cuddihy, 1999; LANDFIRE, 2016)	Elevation (m) (Gagne and Cuddihy, 1999; LANDFIRE, 2016)	Characteristic plants (Gagne and Cuddihy, 1999; LANDFIRE, 2016)
Dry cliff	50–150	15–3000	<i>Heteropogon contortus</i> (pili), <i>Peperomia tetraphylla</i> (kupali'i), <i>Trisetum glomeratum</i> (pili uka, mountain pili), <i>Artemisia mauiensis</i> (hinahina), and <i>Psydrax odorata</i> (alahe'e)
Lowland dry grassland	10–175	Generally 30 and sparingly up to 2000	Pili and <i>Eragrostis monticola</i> (kalamālō)
Lowland dry shrubland	50–170	100–600	alahe'e, <i>Dodonaea viscosa</i> ('a'ali'i), <i>Wikstroemia</i> spp. ('ākia), <i>Bidens</i> spp. (ko'oko'olau), <i>Sida fallax</i> ('ilima), <i>Waltheria indica</i> ('uhaloa), and <i>Sesbania tomentosa</i> ('ōhai)
Montane-subalpine dry grassland	40–50	1615–2300	<i>Eragrostis atropioides</i> (lovegrass) and <i>Panicum tenuifolium</i> (mountain pili)
Montane-subalpine dry shrubland	40–150	900–3000	'a'ali'i, ko'oko'olau, <i>Myoporum sandwicense</i> (naio), <i>Dubautia</i> spp. (na'ena'e), <i>Styphelia tameiameia</i> (pūkiawe), <i>Vaccinium</i> spp. ('ōhelo), <i>Chenopodium oahuense</i> ('āweoweo), and <i>Metrosideros polymorpha</i> ('ōhi'a)
Alpine dry shrubland	75–125	Mainly between 3000 and 3400 but can extend down to 2600 in arid zones	<i>Argyroxiphium sandwicense</i> ('āhinahina, silversword), <i>Dubautia arborea</i> (na'ena'e), and <i>D. menziesii</i> (kūpaoa)

Pre-Human Extent/Range

Prior to human arrival, dry shrublands and grasslands (including dry cliff) occurred on all of the main Hawaiian islands. They were found primarily on the leeward sides of the islands and often in lower elevations (Figs. 1–4). Specifically, they were distributed across northwest and southwest areas of the island of Hawai'i; west and central Maui, and the summit of Haleakalā; lower elevation areas across the islands of Lāna'i and Kaho'olawe; western and central parts of Moloka'i; the Kaiwi coastline, 'Ewa plains, and western parts of O'ahu; western parts of Kaua'i including valleys in the Waimea canyon; and western and eastern parts of Ni'ihau (Figs. 1–4).

In the NWHI, dry shrublands and grasslands were found on the islands of Nihoa and Mokumanamana (Necker). These islands contained a mix of lowland dry grasslands and shrublands; as well as dry cliffs. They were likely composed of primarily lowland native species such as *Sida fallax* ('ilima), *Chenopodium oahuense* ('āweoweo), and *Sesbania tomentosa* ('ōhai) (PMNM, 2008). Based on numerous descriptions of the islands from ships logs and studies (Bryan, 1978), we speculate that mixed lowland dry grasslands and shrublands, and dry cliffs covered the majority of Nihoa and Mokumanamana. There were also sparse pockets of coastal mesic forests containing species like *Pandanus tectorius* (hala) and *Pritchardia* spp. (loulou).

Viability of Pre-Human Dry Grasslands and Shrublands

Historically, dry grasslands and shrublands were distributed across all of the main Hawaiian islands, with smaller ranges across individual islands like Kaua'i, O'ahu, and the island of Hawai'i (Figs. 1–4). Dry cliffs and lowland dry grasslands and shrublands were widely distributed, however, montane-subalpine dry grasslands and shrublands and alpine shrublands were limited mostly to Maui. This smaller size and distribution left montane-subalpine dry grasslands and shrublands less redundant, and therefore less tolerant to withstand catastrophic events (i.e., wildfires, lava flows, hurricanes). However, due to the widespread distribution across all of the main Hawaiian islands, the ecotype as a whole was redundant and could have withstood events only affecting individual or a few islands.

Occurring primarily on the leeward sides of the main Hawaiian islands, dry grasslands and shrublands were represented in relatively large areas. In the NWHI, the size of this ecotype was much smaller, given the size of the islands (Nihoa and Mokumanamana). In addition, species richness was considered low to moderate so although it was composed entirely of native vegetation, it may not have been of the highest quality. However, the large size of this ecotype in the main Hawaiian islands made it resilient to stochastic events like flooding or minor fires. Dry grasslands and shrublands in the NWHI were less resilient due to their smaller size.

Given that pre-human dry grasslands and shrublands were found primarily on the leeward sides of islands and in lower elevations, the features of this ecotype (i.e., geographic, ecological, climatic) are not very representative of those found throughout the Hawaiian islands. Therefore the species richness and genetic variability needed to survive across their ecological environment over time (representation) would have been low.

Fig. 1 Map of historic and current extent of dry grasslands and shrublands on the island of Hawai'i.

Current Condition

Dry Grassland and Shrubland Sub-Types

Before the arrival of humans, dry grasslands and shrublands were represented by six native sub-types. This is now further subdivided to include two more sub-types, which are introduced dry grassland and introduced dry shrubland. While five of the pre-human sub-types (lowland grasslands and shrublands, montane-subalpine grasslands and shrublands, and alpine shrublands) remain characterized by native species, dry cliff now includes introduced plant species. These changes and the two new sub-types are described in [Table 2](#) below.

Fig. 2 Map of historic and current extent of dry grasslands and shrublands on the islands of Moloka'i, Lāna'i, Maui, and Kaho'olawe.

Fig. 3 Map of historic and current extent of dry grasslands and shrublands on the island of O'ahu.

Fig. 4 Map of historic and current extent of dry grasslands and shrublands on the islands of Kaua'i and Ni'ihau.

Table 2 New current condition dry grassland and shrubland sub-types.

Sub-type	Precipitation (cm) (Gagne and Cuddihy, 1999; LANDFIRE, 2016)	Elevation (m) (Gagne and Cuddihy, 1999; LANDFIRE, 2016)	Characteristic plants (Gagne and Cuddihy, 1999; LANDFIRE, 2016)
Dry cliff	50–150	15–3000	Pili, kupali'i, pili uka (mountain pili), hinahina, alahe'e, <i>Melinis repens</i> (natal redtop), <i>Lantana camara</i> (lantana), <i>Leucaena leucocephala</i> (koa haole), and <i>Prosopis pallida</i> (kiawe)
Introduced dry grassland	Varies	Typically in lowlands, but extends to montane-subalpine areas	<i>Pennisetum setaceum</i> (fountain grass), <i>Cenchrus ciliaris</i> (buffelgrass), <i>Megathyrsus maximus</i> (guinea grass) <i>Andropogon virginicus</i> (broomsedge), <i>Schizachyrium condensatum</i> (beardgrass), natal redtop, and <i>Hyparrhenia rufa</i> (thatching grass); often mixed with kiawe in the overstory
Introduced dry shrubland	Varies	Lowlands through montane-subalpine	<i>Plantago lanceolata</i> (plantain), <i>Hypochoeris radicata</i> (cat's ear), <i>Heterotheca grandiflora</i> (telegraph weed), <i>Tagetes minuta</i> (marigold), and <i>Verbesina encelioides</i> (golden crownbeard)

Current Extent/Range

Distribution by sub-type

Dry cliff

Dry cliffs are currently found on all of the main Hawaiian islands except Ni'ihau, as well as Nihoa and Mokumanamana in the NWHI. Unlike their pre-human state of native vegetation, these sites are now often weedy and may contain introduced plant species like *Melinis repens* (natal redtop), *Lantana camara* (lantana), *Leucaena leucocephala* (koa haole), and *Prosopis pallida* (kiawe) (LANDFIRE, 2016).

Native dry grasslands and shrublands

Lowland native dry grasslands are found primarily on the dry leeward sides mostly on the islands of Lāna'i, Maui, Kaho'olawe, and Hawai'i (Gagne and Cuddihy, 1999). They are also found on Nihoa and Mokumanamana in the NWHI. The dominant native grass in this sub-type is pili which is fairly widespread in areas dominated by native species, including the understory of native dry shrublands (LANDFIRE, 2016). Most of the lowland dry grasslands are now primarily composed of nonnative species (Gagne and Cuddihy, 1999) and are characterized as introduced dry grasslands described below.

Lowland native dry shrublands occur on the leewards sides of all of the main Hawaiian islands, as well as Nihoa and Mokumanamana (LANDFIRE, 2016). Montane-subalpine native dry grasslands and shrublands are limited to dry slopes of high mountains like Haleakalā on Maui, and Mauna Kea, Mauna Loa, and Hualālai on the island of Hawai'i (LANDFIRE, 2016). Similarly, alpine native dry shrublands are found only on the high slopes of Maui and the island of Hawai'i (Gagne and Cuddihy, 1999; LANDFIRE, 2016).

Introduced dry grasslands and shrublands

Introduced dry grasslands and shrublands occur predominantly on the leeward sides of all the main Hawaiian islands (Gagne and Cuddihy, 1999; LANDFIRE, 2016). These sub-types are characterized as being dominated by introduced grasses or introduced shrubs.

Overall extent/range

Currently, native dry grasslands and shrublands still occur on all of the main Hawaiian islands, as well as Nihoa and Mokumanamana in the NWHI. However, the extent has changed since pre-human conditions (Figs. 1–4). One factor contributing to these changes are the introductions of nonnative species, which resulted in new sub-types referred to as introduced grasslands and shrublands that were likely once forest. There are still remnants of native-dominated dry grasslands and shrublands but they are greatly reduced in size, as introduced grasslands and shrublands have become very widespread (Fig. 6).

There is a total of 750,222 acres (ac) (303,604 hectares (ha)) of dry grasslands and shrublands in the main Hawaiian islands. The island of Hawai'i contains more than 462,000 ac (186,965 ha) of dry grasslands and shrublands, the most in the main Hawaiian islands, followed by Moloka'i with approximately 75,000 ac (30,351 ha) (Fig. 5 and Table 3). Roughly 164,090 ac (66,405 ha) or approximately 22% of dry grasslands and shrublands in Hawai'i are native dominated (greater than 50% of the total vegetation cover is native vegetation), with the majority (147,636 ac (59,746 ha)) located on the island of Hawai'i (Fig. 6). In comparison,

Fig. 5 Distribution of dry grasslands and shrublands in the main Hawaiian islands.

Table 3 Current distribution of dry grasslands and shrublands in the main Hawaiian islands (Reeves and Amidon, 2018).

Island	Area (Acres)	Percent of island	Percent of main Hawaiian islands
Kaho'olawe	8611	30	< 1
Ni'ihau	6948	15	< 1
Lāna'i	46,839	52	1
Moloka'i	74,744	46	2
Kaua'i	33,951	10	1
O'ahu	51,029	14	1
Maui	66,058	14	2
Hawai'i	462,042	18	11

**Fig. 6** Quality of dry grasslands and shrublands in the main Hawaiian islands.

approximately 486,958 ac (197,065 ha) or 65% of dry grasslands and shrublands in Hawai'i are native/nonnative mix and 55,113 ac (22,304 ha) or 7% are classified as heavily disturbed (Fig. 6).

In the NWHI, Nihoa and Mokumanamana are primarily made up of dry cliff and lowland dry grasslands and shrublands that are still dominated by native vegetation. These islands are highly significant in Hawaiian culture and are home to numerous cultural sites, suggesting they were visited by Hawaiians (PMNM, 2008). There is also evidence that habitation occurred for short periods of time, but most of the island, particularly on Nihoa, was unsuitable for cultivation. As a result, much of the natural ecosystem remained intact (USFWS, 1998).

Stressors

There are a number of stressors that impact dry grasslands and shrublands. Four of the most significant stressors are described below, followed by other less significant stressors.

Invasive ungulates

Introduced ungulates have greatly impacted the native vegetation of the Hawaiian islands. These impacts were accelerated following the arrival of Captain James Cook in 1778. The Cook expedition and subsequent explorers intentionally introduced a European race of pigs or boars and other livestock, such as goats (Tomich, 1986; Loope, 1998). Other ungulates now present in Hawai'i include

axis deer, black-tailed deer, mouflon, sheep, and cattle. The mild climate of the islands, combined with the lack of competitors or predators, led to the successful establishment of large populations of these invasive ungulates. The presence of these species is considered one of the primary factors underlying the alteration and degradation of native plant communities and habitats in the Hawaiian islands.

Dry grasslands and shrublands are exposed to both direct and indirect negative impacts of invasive ungulates. This includes the destruction of vegetative cover, trampling of plants and seedlings, direct consumption of vegetation, soil disturbance, dispersal of nonnative plant seeds, and creation of open disturbed areas conducive to further invasion by invasive plant species. All of these impacts lead to the subsequent conversion of a plant community dominated by native species to one dominated by invasive species, thus increasing the area of introduced grasslands and shrublands. In addition, because ungulates inhabit terrain that is often steep and remote, foraging and trampling contributes to severe erosion of watersheds and degradation of streams (Cuddihy and Stone, 1990).

Invasive plants

Native vegetation on all of the main Hawaiian islands has undergone extreme alteration because of past and present land management practices, the deliberate introduction of nonnative plants and animals, and agricultural development (Cuddihy and Stone, 1990). After human contact with Hawai'i, over 800 plant taxa have been introduced from elsewhere, and nearly 100 of these have become pests (Smith, 1985; Cuddihy and Stone, 1990). Some of the nonnative plants were brought to Hawai'i by various groups of people, including ranchers that intentionally introduced pasture grasses and other nonnative plants for agriculture, and sometimes inadvertently introduced weeds as well. These pasture grasses and invasive weeds often took over and dominated native dry grasslands and shrublands. As a result, much of the native plant species biodiversity was lost, while invasive plant species increased (Scott et al., 1986; Cuddihy and Stone, 1990).

Invasive plants can adversely affect microhabitat in dry grasslands and shrublands by modifying availability of light and nutrient cycling processes, altering soil-water regimes, altering fire characteristics of native plant habitat leading to incursions of fire-tolerant nonnative plant species, and outcompeting native plant species. Each of these effects can convert native-dominated plant communities to nonnative plant communities. Additionally, some invasive plants may release chemicals that inhibit growth of other plants (Cuddihy and Stone, 1990; Vitousek, 1992).

Invasive herbivores

The primary invasive herbivores that impact the dry grasslands and shrublands are rats. There are three species of rats, all of which are introduced, in the Hawaiian islands: the Polynesian rat (*Rattus exulans*), black rat (*Rattus rattus*), and Norway rat (*Rattus norvegicus*). Rats are omnivorous and eat almost any type of food (Nelson, 2012). They impact plants by eating fleshy fruits, seeds, flowers, stems, leaves, roots, and other plant parts (Atkinson and Atkinson, 2000), and by stripping bark and cutting small branches (twig cutting) in search of moisture and nutrients, seriously affecting vigor and regeneration (Abe and Umeno, 2011; Nelson, 2012). In the Hawaiian islands, rats may consume as much as 90% of the seeds produced by some native plants, and in some cases prevent regeneration of forest species completely (Cuddihy and Stone, 1990), which can result in the creation of barren areas that allow the spread of introduced grasslands and shrublands.

Fire and drought

Fires inadvertently or intentionally set by the Polynesian settlers probably contributed to the initial decline of native vegetation in the drier plains and foothills. These early settlers practiced slash-and-burn agriculture that created open lowland areas suitable for the opportunistic invasion and colonization of nonnative, fire-adapted grasses (Kirch, 1982; Cuddihy and Stone, 1990). Ranching and the creation of pasture lands in particular created highly fire-prone areas of nonnative grasses and shrubs (D'Antonio and Vitousek, 1992). Although fires were infrequent in mountainous regions, extensive fires have recently occurred in lowland dry areas, leading to grass-fire cycles that convert native dry forest to invasive grassland (D'Antonio and Vitousek, 1992).

Because of the greater frequency, intensity, and duration of fires that have resulted from the human alteration of landscapes and the introduction of nonnative plants, especially grasses, fires are now more destructive to native Hawaiian ecosystems (Brown and Smith, 2000), and a single grass-fueled fire often kills most native plants in the area (D'Antonio and Vitousek, 1992). Fire destroys dormant seeds of these native species, as well as the individual plants and animals themselves, even in steep, inaccessible areas or near streams and ponds. Successive fires remove habitat for native species by altering microclimate conditions, creating conditions more favorable to invasive plants. Invasive grasses (e.g., fountain grass), many of which may be fire-adapted, produce a high fuel load that allow fire to burn areas that would not otherwise burn easily, regenerate quickly after fire, and establish rapidly in burned areas, thus outcompeting native plants and inhibiting their regeneration (Fujioka and Fujii 1980 in Cuddihy and Stone, 1990, Tunison et al., 2002). Native woody plants may recover to some degree, but fire tips the competitive balance toward invasive species (National Park Service 1989 in Cuddihy and Stone, 1990). Due to the seasonal drought conditions in the dry grasslands and shrublands, the risk of fire and its associated impact is exacerbated and considered a significant stressor.

Other stressors

Natural disasters like hurricanes exacerbate the impacts from other threats such as habitat modification and destruction by ungulates and competition with nonnative plants. By destroying vegetation, hurricanes open the forest canopy, thus modifying the availability of light, and create disturbed areas conducive to invasion by nonnative pest species (Asner and Goldstein, 1997;

Harrington et al., 1997). Additionally, changes in environmental conditions that may result from global climate change include increasing temperatures, changing precipitation, and increasing storm intensities. These changes may lead to the loss of native species due to direct physiological stress, the loss or alteration of habitat, or changes in disturbance regimes (e.g., droughts, fire, storms, and hurricanes) (Fortini et al., 2013).

Past land use practices such as agricultural or urban development have resulted in little or no native vegetation below 2000 ft. (600 m) throughout the Hawaiian islands (TNCH, 2007), largely impacting lowland dry grasslands and shrublands. The development of irrigation systems has allowed for areas that were once dry grasslands and shrublands to be converted to farming and ranching lands. Although agriculture has been declining in importance, these large tracts of former agricultural lands are now being converted into residential areas or left fallow (TNCH, 2007). Forests were also converted to grasslands for ranching or grazing cattle (Cuddihy and Stone, 1990). In addition, the population in Hawai'i has increased almost 10% in the past 10 years, further increasing demands on limited land and water resources in the islands (HDBEDT, 2013).

Conservation Efforts

Conservation efforts attempt to provide some relief from stressors. These efforts are implemented by numerous government agencies (federal and State), private organizations, and non-governmental organizations (NGOs). Given that land ownership varies (Fig. 7), many partnerships are formed to collectively manage dry grasslands and shrublands. The goals of management vary by site, but may be to restore existing native dry grassland and shrubland or to restore sites back to dry forest. The following subsections describe some of the conservation efforts related to dry grasslands and shrublands, however they do not encompass all that exist (Table 4).

Federal

There are a number of federal agencies that are involved in the management of dry grasslands and shrublands (Table 4). Pōhakuloa Training Area (PTA) is a vitally important training area to the U.S. military in the Pacific and also home to large tracts of tropical subalpine dryland ecosystems and dozens of threatened and endangered plants, birds, and bats. Large-scale fences at PTA span > 37,298 ac (15,094 ha) which include montane-subalpine dry grasslands and shrublands (U.S. Army Garrison, 2016). The Kahuku Unit of Hawai'i Volcanoes National Park (HVNP) expands across lava fields, pastures, forests, shrubland and mesic, subalpine, alpine, and desert environments (National Park Service, 2015). Much of Haleakalā National Park contains montane-subalpine

Fig. 7 Land ownership of dry grasslands and shrublands in the main Hawaiian islands.

Table 4 Examples of conservation efforts in dry grasslands and shrublands.

<i>Organization/agency name</i>	<i>Location, island</i>	<i>Organization type</i>	<i>Conservation efforts</i>	<i>Target stressor(s)</i>
U.S. Department of Defense	Pōhakuloa Training Area, Hawai'i	Federal	Fencing, invasive plant and ungulate management, fire prevention, propagation and outplanting	Invasive species, fire
National Park Service	Hawai'i Volcanoes National Park, Hawai'i	Federal	Fencing, ungulate control, restoration	Invasive species
National Park Service	Haleakalā National Park, Maui	Federal	Fencing, ungulate removal, invasive predator and plant control, surveys for listed species	Invasive species
U.S. Fish and Wildlife Service	Kalaeloa Unit of Pearl Harbor National Wildlife Refuge, O'ahu	Federal	Invasive plant control, fire break management, outplanting	Invasive species, Fire
Hawai'i Department of Land and Natural Resources	Mauna Kea Forest Reserve, Hawai'i	State	Fencing, invasive plant and ungulate control, fire control, surveys and monitoring, reforestation	Invasive species, fire
Department of Hawaiian Home Lands	Āina Mauna Legacy Program, Hawai'i	State	Invasive species removal, reforestation and restoration, conserving endangered species, providing educational and cultural opportunities	Invasive species
Kamehameha Schools	Lupea, Hawai'i	Private	Fencing, invasive species control, outplanting and restoration	Invasive species
Kamehameha Schools	Keauhou, Ka'ū, Hawai'i	Private	Fencing, ungulate removal, invasive plant and predator control, fire management, outplanting and restoration	Invasive species, fire
Pūlama Lāna'i	Lāna'i	Private	Invasive plant and animal control, fire management, propagation and outplanting	Invasive species, Fire
Hawai'i Association of Watershed Partnerships—Mauna Kea Watershed Alliance	Mauna Kea Forest Reserve, Hawai'i	Multi-agency Partnership	Fencing, invasive plant and ungulate control, fire control, surveys and monitoring, reforestation	Invasive species, fire
Hawai'i Association of Watershed Partnerships – Wai'anae Mountains Watershed Partnership	Mākaha Valley, O'ahu	Multi-agency Partnership	Invasive plant and predator control, fire management	Invasive species, fire
Invasive Species Committees – O'ahu Invasive Species Committee	Various locations, O'ahu	Multi-agency Partnership	Invasive plant and predator control, fire management	Invasive species, fire
Papahānaumokuākea Marine National Monument	Nihoa and Mokumanamana (Necker)	Multi-agency Partnership	Invasive plant management, research and monitoring	Invasive species

native dry grasslands and shrublands, as well as alpine shrublands. Restoration in the Nu'u parcel on the leeward slope of Haleakalā includes removal of feral ungulates and the construction of an ungulate-proof fence enclosing approximately 2115 ac (856 ha) ([Haleakalā National Park, 2016](#)). On O'ahu, the Kalaeloa Unit of the Pearl Harbor National Wildlife Refuge contains introduced dry grasslands in the lowlands along the coast. Weed control is often implemented for invasive grasses, as well as outplanting of native dryland shrub species like 'ilima.

State

The State of Hawai'i Department of Land and Natural Resources (DLNR) lands are made up of forest reserves, wildlife sanctuaries, Natural Area Reserves (NAR), State recreation areas, and a research reserve. The State conducts some conservation management actions on these lands and provides access to others who are conducting such activities. On the island of Hawai'i, the Mauna Kea Forest Reserve consists of dry subalpine and alpine communities and is just one example of an area where the State implements conservation efforts for this ecotype ([HDLNR, 2015](#)).

The Department of Hawaiian Home Lands (DHHL) was created by the Hawai'i State Legislature in 1960 and is governed by the Hawaiian Homes Commission Act of 1920. The act set aside a land trust for native Hawaiians to maintain their traditional ties to the land. DHHL views part of its responsibility as a landowner to manage and protect native lands "to support both cultural and resource management activities and create homesteading opportunities for the future" ([DHHL, 2009](#)). Thus, the 'Āina Mauna Legacy Program was created to protect habitat on Mauna Kea on the island of Hawai'i. The program specifically includes the lands of Humu'ula and Pi'ihonua, which contain tracts of dry grassland and shrubland ([DHHL, 2009](#)).

Private

Kamehameha Schools (KS) is the largest private landowner in the State of Hawai'i with landholdings of over 365,000 ac (147,710 ha). Approximately 99% of this land is designated for agricultural (176,890 ac) or conservation (181,675 ac) purposes. In addition, roughly 51,000 ac (20,640 ha) or 14% is classified as dry grassland and shrubland with the majority located in the Kona district and Keauhou, in the Ka'u district of the island of Hawai'i.

On the Kona side of the island of Hawai'i, KS implements active restoration and management of dry grasslands and shrublands in Lupea through collaboration with the Three Mountain Alliance and Hawaiian Silversword Foundation (*Kamehameha Schools, 2011*). In Keauhou, Ka'u, a Safe Harbor Agreement between KS, DLNR, and the U.S. Fish and Wildlife Service (USFWS) was signed in June of 2018. The total area covered by the agreement is 32,207 ac (13,034 ha) which includes dry grasslands and shrublands. The 50-year agreement will contribute to the recovery of 32 endangered species (17 endangered plants, 7 endangered animals, and one threatened animal). The agreement is part of an ongoing watershed partnership effort within the State of Hawai'i managed by the Three Mountain Alliance Watershed Partnership (*TMA, 2007*).

The island of Lāna'i is almost entirely under private ownership but does have conservation partnerships with the USFWS, the state of Hawai'i, and The Nature Conservancy. Currently the land manager, Pulamā Lāna'i, is implementing actions that benefit dry grassland and shrubland such as protecting the dry habitat within a designated Lowland Ecosystem Area totaling at least 2000 ac (809 ha) in size (*Lāna'i Resorts et al., 2015*).

Multiple agency partnerships

The Hawai'i Association of Watershed Partnerships (HAWP) are voluntary alliances of public and private landowners committed to protecting over 2 million ac (809,371 ha) of the most important watershed lands in Hawai'i. Individual watershed partnerships have been established on five islands (island of Hawai'i, Maui, Moloka'i, O'ahu, and Kaua'i) and jointly form HAWP, to support statewide needs. A number of watershed partnerships work to conserve dry grasslands and shrublands, some of which are included in *Table 4*.

Invasive species committees (ISCs) are voluntary partnerships of government, private and non-profit organizations, and concerned individuals working to address invasive species issues in Hawai'i. These committees have been formed on individual islands (island of Hawai'i/Big Island [BIISC], Maui [MISC], Moloka'i [MoMISC], O'ahu [OISC], Kaua'i [KISC]) and focus on the specific issues of their island. The overall goal of the ISCs is to "prevent, eradicate, or control priority incipient plant and animal species that threaten Hawai'i's most intact federal, state, and private conservation lands" (*HDLNR, 2015*). A typical approach taken by the ISCs is to identify the priority invasive species and then implement control and/or eradication.

Nihoa and Mokumanamana are located within the Papahānaumokuākea Marine National Monument (PMNM), which is managed by the following co-trustees: DLNR, USFWS, National Oceanic and Atmospheric Administration (NOAA), and Office of Hawaiian Affairs (OHA). Together, the co-trustees manage the dry grasslands, dry shrublands, and dry cliffs on these two islands. Access into the monument is very limited and visits to Nihoa or Mokumanamana are typically only for research, monitoring, or cultural purposes. In addition, both of these islands are designated as critical habitat for federally listed endangered plants (*HDLNR, 2015*).

Laws and regulations**Endangered Species Act**

The Endangered Species Act of 1973 (ESA) aims to provide a framework to conserve and protect endangered and threatened species and their habitats. As habitat loss is the primary threat to most imperiled species, the ESA allowed the U.S. Fish and Wildlife Service (USFWS) and National Marine Fisheries Service (NMFS) to designate specific areas as protected critical habitat zones. In 1978, Congress amended the law to make critical habitat designation a mandatory requirement for all threatened and endangered species listed under the Act.

Approximately 80,800 ac (32,700 ha) or 11% of dry grasslands and shrublands have been designated as federal critical habitat in the main Hawaiian islands (*Fig. 8*). The majority of designated critical habitat that is also classified as dry grasslands and shrublands is located on the island of Hawai'i at 53,408 ac (21,613 ha) (*Fig. 8*). Species listed under the Federal Endangered Species Act are automatically added to the State of Hawai'i list of endangered species, and are thus also protected by State regulations.

Biosecurity and invasive species control

As described above, invasive species are a major stressor to dry grasslands and shrublands. In addition to implementing invasive species control, biosecurity measures that prevent the introduction of invasive species are critical. *Table 5* provides a list of laws and regulations that address the issue of invasive species in Hawai'i. These laws and regulations not only benefit this ecotype, but all other ecotypes impacted by invasive species in Hawai'i.

Protected areas

Approximately 45,533 ac (18,426 ha) or 6% of dry grasslands and shrublands are protected in reserve areas in the main Hawaiian islands (*Fig. 9*). Reserve areas are defined as areas that are designated as parks or reserves such as a national park, national wildlife refuge, or NAR (*Reeves, 2018*). In the main Hawaiian islands, the island of Hawai'i has the most dry grasslands and shrublands in reserve areas with 33,641 ac (13,614 ha) or 7% of the total ecotype on the island (*Fig. 9*). This is followed by Maui with 7266 ac (2940 ha) or 11% of the islands ecotype (*Fig. 9*). In regards to the NWHI, Nihoa and Mokumanamana are protected within the PMNM.

Fig. 8 Federally designated critical habitat in dry grasslands and shrublands across the main Hawaiian islands.

Viability of Current Dry Grasslands and Shrublands

Before the arrival of humans, dry grasslands and shrublands were distributed widely and covered relatively large areas in the main Hawaiian islands. These characteristics resulted in the ecotype as a whole being resilient and redundant. However, the features of this ecotype were not very widely distributed and biodiversity was low to moderate, which gave it low representation. Currently, the viability of the native sub-types have mostly decreased due to the stressors described above while introduced sub-types have been well established and continue to increase.

Lowland native dry grasslands and shrublands have reduced in size and distribution, and therefore have reduced in redundancy. The overall quality of this sub-type has also declined, resulting in a decrease in resiliency. Most of this reduction is a result of the spread of introduced dry grasslands and shrublands occurring mostly in the lowlands. Fragmentation from other stressors (as described above) has also led to a decrease in genetic range of variability and species diversity, and therefore a decrease in representation. This decrease in redundancy, resiliency, and representation has also occurred for dry cliff and montane-subalpine native dry grasslands and shrublands, but to a lesser extent.

Alpine native dry shrublands historically occurred only on Maui, and now occur on the island of Hawai'i as well (Figs. 1–4). This increased distribution has slightly increased its redundancy and representation compared to pre-human contact. However, as the stressors described above impact this sub-type, the size and distribution of this sub-type is decreasing, thus its redundancy and representation is also decreasing. In addition, the quality of this sub-type has also decreased due to the impact of human-caused stressors, which has reduced its resiliency.

Introduced grasslands and shrublands currently have the largest size and distribution among all of the sub-types. The stressors described above have resulted in the establishment and spread of these introduced sub-types throughout the main Hawaiian islands. Their large size and distribution throughout the range of islands has resulted in introduced grasslands and shrublands having the highest level of redundancy, resiliency, and representation among Hawai'i's dry grasslands and shrublands (Table 6).

Future Scenarios

The condition of dry grasslands and shrublands in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

Table 5 Laws and regulations that address invasive species in Hawai'i.

<i>Title</i>	<i>Year implemented</i>	<i>Authority</i>	<i>Intent/purpose</i>
50 CFR 16	1974	Federal	Implements the Lacey Act (18 USC 42), which prohibits importation of injurious species
Convention on International Trade in Endangered Species	1975	International	Ensures that international trade in specimens of wild animals and plants does not threaten the survival of the species in the wild
Executive Order 11987	1977	Federal	Charges executive agencies with restricting the introduction of exotic species into the natural ecosystems on federal lands; and encourages States to do the same
Hawai'i Administrative Rules, Title 4, Subtitle 6, Chapters 68 and 70	1981	Hawai'i (Department of Agriculture)	Rules/amendments for noxious weeds, plant and non-domestic animal quarantine, plant import, and bromeliad import
Executive Order 13112	1999	Federal	Requires that a Council of Departments dealing with invasive species be created to prevent the introduction of invasive species and provide for their control and to minimize the economic, ecological, and human health impacts that invasive species cause
HRS 194-2	2002	Hawai'i (Department of Land and Natural Resources)	Establishes Hawaii Invasive Species Council (HISC)
Act 85	2003	Hawai'i (HISC)	Conveys statutory authority to HISC to continue to coordinate approaches among the various State and Federal initiatives for the prevention and control of invasive species
Act 36 (2011) HRS 150A-5.3	2011	Hawai'i (DOA)	Imposes a fee for the inspection, quarantine, and eradication of invasive species contained in any freight brought into the State
HB 1568	2011	Hawai'i (DOA)	Requires commercial harbors and airports in Hawai'i to provide biosecurity and to facilitate cargo inspections
Executive Order 13751	2016	Federal	To prevent the introduction of invasive species and provide for their control, and to minimize the economic, plant, animal, ecological, and human health impacts that invasive species cause (amends EO 13112)
7 CFR 360.200	2018	Federal	Designates certain plants as noxious weeds

1. Conservation Values: stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
2. Laws and Biosecurity: national, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented. (e.g. hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
3. Development or Conservation Planning: national, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the "foreseeable future" (Miller, 2018), and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuren et al., 2011a,b).

The four foreseeable future scenarios being considered by federal, State, private and multiple agency partners are:

Future Scenario One, Status Quo—the most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future.

Future Scenario Two—a slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future Scenario Three—a slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Fig. 9 Quality of dry grasslands and shrublands designated as reserve areas in the main Hawaiian islands.

Table 6 Summary of change in dry grassland and shrubland viability from pre-human to current.

<i>Sub-type</i>	<i>Redundancy</i>	<i>Resiliency</i>	<i>Representation</i>
Dry cliff	Decrease	Decrease	Decrease
Lowland native dry grassland	Decrease	Decrease	Decrease
Lowland native dry shrubland	Decrease	Decrease	Decrease
Montane-subalpine native dry grassland	Decrease	Decrease	Decrease
Montane-subalpine native dry shrubland	Decrease	Decrease	Decrease
Alpine native dry shrubland	Decrease	Decrease	Decrease
Introduced dry grassland	Increase	Increase	Increase
Introduced dry shrubland	Increase	Increase	Increase

Future Scenario Four—a moderate to high increase in conservation actions in the CMPs substantially improves conservation management.

We analyzed the future viability of the dry grasslands and shrublands in Hawai'i under these four future scenarios using a series of analyses of land cover maps and projected changes over time. The future condition of dry grasslands and shrublands in Scenario One, the status quo, was characterized from an assessment of change over time in dry grassland and shrubland land cover obtained from existing land cover maps (Amidon and Reeves, 2018). Based on these land cover maps, an annual rate of change was estimated, and a projected change (in acres/ha) was calculated for the year 2035. The resulting information on changes in land cover by 2035, as derived from existing land cover change estimates, is the extent of dry grasslands and shrublands that is expected in the foreseeable future under Scenario One, the status quo, where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged.

The future conditions of dry grasslands and shrublands for Scenarios Two, Three, and Four cannot be quantitatively (acres/ha) estimated. However, the Scenario One estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of dry grasslands and shrublands under Scenarios Two, Three, and Four. Changes in human population are captured only by the changes in the “developed” land cover footprint derived from land cover map analysis (Amidon and Reeves, 2018). Impacts

from other sources of human activities or human-caused stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by non-native vegetation. For an assessment of island-by-island changes in human population, see [Amidon and Reeves \(2018\)](#).

Also, note that island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions which occurs on the order of centuries rather than years ([Solomon et al., 2009](#); [Gillett et al., 2011](#)). Evidence of climate effects is also confounded by the large annual variation in the Pacific islands climate parameters, which is much greater than projected climate change by 2035. Although impacts from climate-related stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future viability.

Future Scenario One—Status Quo

Scenario One is considered the most likely future scenario, and serves as a “baseline” for comparing among the four future scenarios. There is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in the dry grassland and shrubland sub-types ([Table 7](#)).

In Scenario One, the viability of all native sub-types of grasslands and shrublands (lowland, montane-subalpine, alpine) are predicted to decrease from their current state ([Table 8](#)). Since these sub-types are currently confined to the leeward sides of islands or the dry, high elevation areas on Maui and the island of Hawai'i, we predict their abundance will continue to decline in area (redundancy and representation). Human-caused stressors will increase overall ([Table 7](#)) and continue to reduce native composition. With the increased potential of invasive species, the ecological function of the native sub-types is expected to decrease due to the ability of invasive species to outcompete native species for water and space. As a result, native biodiversity in these sub-types including dry cliffs will also decrease ([Table 8](#)).

Table 7 Responses of dry grassland and shrubland stressors in foreseeable future scenarios.

Conservation management parameters (CMPs)				
Conservation values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans			
Laws and biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented			
Planning for development or conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation)			
Foreseeable future scenarios and the resulting dry grassland and shrubland habitat conditions				
Use Foreseeable Future Scenario One as a “baseline” to characterize changes in <i>Conservation Actions</i> and <i>Habitat Conditions</i> in Future Scenarios Two, Three and Four	Scenario One: <i>CMPs</i> : unchanged in support for NRC/B <i>Conservation actions</i> : no change; current rate of land cover change continues through the foreseeable future <i>Habitat condition</i> : habitat area, quality, and sustainability slowly decrease through the foreseeable future	Scenario Two: <i>CMPs</i> : small increase in support for NRC/B <i>Conservation actions</i> : marginal increase <i>Habitat condition</i> : habitat area is unchanged through the foreseeable future; habitat quality and sustainability are slightly enhanced through the foreseeable future	Scenario Three: <i>CMPs</i> : small to moderate decrease in support for NRC/B <i>Conservation actions</i> : substantial decrease <i>Habitat condition</i> : urban and agricultural uses are prioritized over conservation; habitat area, quality, and sustainability substantially decrease through the foreseeable future	Scenario Four: <i>CMPs</i> : moderate to high increase in support for NRC/B <i>Conservation actions</i> : substantial increase <i>Habitat condition</i> : robust, sustained effort to restore, manage, and expand conservation; habitat area, quality, and sustainability substantially increase through the foreseeable future
Stressors	Responses of dry grassland and shrubland stressors			
Development	Small to moderate increase	No change (redevelop)	Moderate to high increase	Small to moderate decrease
Invasive species	Small increase	Small increase	Higher increase	Small decrease
Plant diseases	Small increase	Small increase	Higher increase	No change to small decrease
Fire	Small increase	Small increase	Higher increase	No change or small increase
Climate				
Temperature	Small to moderate increase	Small to moderate increase	Small to moderate increase	Small to moderate increase
Precipitation	Small decrease	Small decrease	Small decrease	Small decrease
Storms	Small increase	Small increase	Small increase	Small increase

Table 8 Summary of change in dry grassland and shrubland viability in foreseeable future scenarios.

<i>Sub-type</i>	<i>Scenario One: status quo</i>	<i>Scenario Two: slightly improved</i>	<i>Scenario Three: substantially decreased</i>	<i>Scenario Four: substantially improved</i>
Dry cliff	Decrease	Slightly decrease	Severely decrease	Increase
Lowland native dry grassland	Decrease	Slightly decrease	Severely decrease	Increase
Lowland native dry shrubland	Decrease	Slightly decrease	Severely decrease	Increase
Montane-subalpine native dry grassland	Decrease	Slightly decrease	Severely decrease	Increase
Montane-subalpine native dry shrubland	Decrease	Slightly decrease	Severely decrease	Increase
Alpine native dry shrubland	Decrease	Slightly decrease	Severely decrease	Increase
Introduced dry grassland	Slightly increase	Slightly increase	Increase	Decrease
Introduced dry shrubland	Slightly increase	Slightly increase	Increase	Decrease

On the other hand, viability of introduced grassland and shrubland sub-types is expected to slightly increase (Table 8). The increase in introduced invasive species will add to the relative size and distribution of these sub-types. In addition, wildfires are expected to exacerbate these effects as introduced grasses and shrubs tend to recover quicker than native grasses and shrubs, therefore further contributing to a decrease in redundancy and representation of native sub-types. These stressors will essentially result in the continuation of introduced grasslands and shrublands replacing native sub-types and expanding in range.

Future Scenario Two—Slight Increase in CMPs Marginally Improves Conservation Management

In Scenario Two, conservation agencies and stakeholders work with increased but limited resources to slow or stop the degradation of landscape areas. Scenario Two is essentially 'status quo' with minor improvements in the three CMPs. The anticipated changes, under Scenario Two, for each of important stressor are given in Table 7.

In this scenario, native sub-types of dry grasslands and shrublands (lowland, montane-subalpine, alpine), and dry cliff are predicted to slightly decrease in viability from their current state (Table 8). This slight decrease will continue from its current state due to the difficulties of restoring these dry areas. Although there will be minor improvements in the three CMPs, restoration efforts are expected to be negligible as the response time of native vegetation is slow (i.e., reintroduction, augmentation). As a result, we predict the size and distribution of native sub-types will continue to decline in area, thus reducing its viability, but at a slower rate than in Scenario One.

The marginal improvements to conservation management will still result in slight increases to human-caused stressors, except for development (Table 7), as they did in Scenario One. For introduced grasslands and shrublands, the same effects of invasive species and wildfires will result in a slight increase in viability (redundancy, resiliency, and representation), but slightly less than in Scenario One. In addition, this scenario is expected to have the second highest likelihood of occurrence.

Future Scenario Three—Small to Moderate Decrease in CMPs Substantially Decreases Conservation Management

In Scenario Three, all natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in park-like settings or in areas where land development is not possible. This scenario has substantial declines in natural resource conservation within the three CMPs. An increasing human population is supported in its use of land for economic development over the conservation of native habitats. Areas that cannot support development become the only areas of free-living native species. The anticipated changes, under Scenario Three, for each of stressors are given in Table 7.

Due to the limited range (leeward or dry area, and high elevation slopes on Maui and the island of Hawai'i) of native dry grasslands and shrublands, substantial declines in the three CMPs will lead to high levels of degradation and fragmentation. This will result in a decline in the size and distribution of native sub-types at a much faster rate than in Scenario One. The higher increase in invasive species and wildfires will likely significantly alter their ecological structure and function, leading to their severe decrease in viability (Table 8).

The cumulative impacts of these stressors will also lead to an increase in the viability of introduced dry grasslands and shrublands (Table 8). Introduced grasslands and shrublands will continue to replace and outcompete native sub-types and generally expand in range, but at a much faster rate than in Scenario One. Additionally, the increase in development will reduce the overall size and distribution of all sub-types. This scenario will result in the highest impact to resiliency, redundancy, and representation of all future scenarios for all sub-types. However, this scenario, along with Scenario Four has the lowest likelihood of occurring in the foreseeable future.

Future Scenario Four—Moderate to High Increase in CMPs Substantially Improves Conservation Management

In this scenario, a substantial emphasis on natural resource conservation is present in the three CMPs, reflecting increased societal concern for declines in natural habitats and biodiversity. Active and well-supported natural resource management begins to restore these habitats and ecosystems and expand their landscape areas. The anticipated changes, under Scenario Four, for each of the stressors are given in [Table 7](#).

As conservation actions are identified, prioritized, and expanded, the size and abundance of native dry grassland and shrubland sub-types (including dry cliffs) will gradually increase over time, thus increasing its redundancy and resiliency. As stressors are reduced and managed, the ecological structure and function of native sub-types will be maintained in existing areas and increase as they expand. This will contribute to an overall increase in native biodiversity, and increase in representation. Thus, the overall viability of native dry grasslands and shrublands is expected to increase.

Scenario Four is the only future scenario that introduced grasslands and shrublands are predicted to decrease in viability ([Table 8](#)). The decrease in stressors and substantial increase in active restoration, will allow native sub-types to replace introduced grasslands and shrublands, resulting in an overall reduction in the size and distribution of introduced sub-types. In addition, development is expected to decrease, thus opening the potential for more restoration of native dry grassland and shrubland. However, like Scenario Three, this scenario has the lowest likelihood of occurring in the foreseeable future.

Conclusion

Conservation efforts by federal, State, private and multiple agency partnerships have been beneficial in helping to conserve and protect the remaining dry grasslands and shrublands in Hawai'i and the NWHI. While these efforts have helped to recover some of this ecotype through a combination of restoring back to native-dominated dry grasslands and shrublands and dry forests, more collaborative actions are likely needed to increase protection.

The primary stressors impacting dry grasslands and shrublands include habitat destruction and modification by invasive species (ungulates, plants, herbivores), and fire and drought. Despite protected areas and active management by numerous conservation groups to target these stressors, they are expected to continue or increase in magnitude and intensity in the future. It is likely that without continued or increased active management, native dry grasslands and shrublands will continue to be degraded or destroyed in the future while introduced dry grasslands and shrublands will likely stay stable or increase.

Abstract

This article provides an overview of the wet grassland and shrubland biome of the Hawaiian Islands, and includes an assessment of its current status, stressors, and future viability. Wet grassland and shrubland in Hawai'i generally have high rainfall and occur on the wet, windward sides of the main Hawaiian Islands in montane and lowland zones (Gagné and Cuddihy, 1990). Native wet grassland and shrubland consists of wet sedgelands and grasslands, dominated by different *Carex* species and native grasses, and native shrubland that occurs primarily on ridge crests and steep cliffs. The main stressors to this

biome are introduced ungulates (goats, pigs, and sheep), invasive plants, and natural disasters (i.e., hurricanes or landslide). With the introduction of ungulates and invasive plants in the 19th and 20th centuries some native wet grassland and shrubland biome became degraded, and communities of introduced grasses and shrubs became established. Conservation management to protect native grassland and shrubland include weed control, fencing, and ungulate removal, and depends on combined efforts of State, Federal, and multiagency organizations and nonprofit organizations and the voluntary support of private landowners. We base our assessment of wet grassland and shrubland viability in the future on the concepts of representation, redundancy, and resiliency, which we define in this article. We examine condition of wet grassland and shrubland biome in the foreseeable future (to year 2035) based on potential changes in three conservation management parameters: funding and public support for conservation management; conservation and biosecurity-related laws; and State/civic planning for conservation planning and land use and development.

Introduction

This article provides an overview of the wet grassland and shrubland biome in the Hawaiian Islands, the ecological factors that have influenced this biome over time and that will into the future, and a status assessment of wet grassland and shrubland that includes current status, stressors, and future viability. Grassland is defined as an area where vegetation is dominated by grass (Poaceae), sedge (Cyperaceae) and/or rush (Juncaceae) species. Shrubland is defined as an area where vegetation is dominated by woody plants generally less than 3 meters (m) in height. The Hawaiian archipelago is the most isolated landmass in the world. Because of this isolation, species were able to fill empty niches not already occupied by other species, which led to speciation (adaptive radiation) and a high rate of species endemism. Approximately 90% of the species in Hawai'i before arrival of humans were endemic (Cuddihy and Stone, 1990). The Hawaiian Islands in addition have remarkable differences in climate, precipitation, and hydrology over very short distances that contribute a wide diversity of biomes including alpine, desert, cloud forest, mesic and dryland forest, and many others (Gagné and Cuddihy, 1990). Invasive species introduced to Hawai'i are an important stressor on Hawai'i's native biomes, including invasive ungulates that cause damage to native plant communities by eating and trampling native plants, and invasive plants that out compete native plants. Hawaiian biomes sustain through redundancy, resiliency, and representation. Redundancy is a biome's ability to withstand a catastrophic event (e.g., hurricanes, catastrophic fire, earthquakes, volcanic eruptions, etc.) through multiple, distributed populations across the landscape (Smith et al., 2018). Resiliency is a biome's ability to withstand environmental stochasticity (random change in environmental conditions) and is related to the growth rate and size of species' populations (Smith et al., 2018). Representation is a biome's ability to adapt to a changing environment over time due to genetic and species diversity and amount of environmental variation within the biome (Smith et al., 2018). The condition of Hawai'i wet grassland and shrubland in the foreseeable future (to year 2035) is based on potential changes in conservation management parameters including conservation values, laws and biosecurity, and land development or conservation planning. These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out and are critical factors that drive the direction and magnitude of natural resource conservation in Hawai'i for in the foreseeable future.

Climate, Hydrology, and Soils

The entire Hawaiian archipelago consists of some 132 islands, including eight larger, younger islands, the "main islands" of Hawai'i, Maui, Kaho'olawe, Moloka'i, Lāna'i, O'ahu, Kaua'i, and Ni'ihau. These main islands are where the Hawai'i wet grassland and shrubland biome occurs. Climate in the Hawaiian archipelago is characterized by mild and equable temperatures year-round, low to moderate humidity, persistence of northeasterly trade winds, and for the main islands, remarkable differences in rainfall within short distances (Wagner et al., 1990). Most areas in the Hawaiian archipelago experience only two seasons. Warmer and drier "summer" weather occurs between about May and September, when the sun is more nearly overhead and the trade winds most persistent. Slightly cooler and wetter "winter" weather occurs between about October and April, when the sun is in the south and the trade winds are often interrupted by other winds and by intervals of widespread cloud cover and rainfall (Wagner et al., 1990). Depending upon their elevation, the mountains of the main Hawaiian Islands obstruct, deflect, and accelerate the flow of air, and due to a low inversion layer and moisture-laden trade winds, create a rainfall pattern known as the orographic effect that produces predictable and substantial precipitation on several of the main Hawaiian Islands. During the daytime and summer months, the tops of the higher Hawaiian mountains are almost constantly obscured by a band of clouds produced in this fashion (Wagner et al., 1990). In addition to rainfall, the primary factor driving the complexity and diversity of hydrological conditions observed in Hawai'i is the highly permeable nature of the islands' volcanic substrates, an attribute particularly prevalent on the younger islands of Hawai'i and Maui (Juvik and Juvik, 1998). Substrate permeability varies considerably and in some rift zones of the mountains of the main islands, very hard, dense, and highly impermeable dike rock formations capture and hold large volumes of groundwater. This trapped groundwater slowly percolates through the rock horizontally toward areas of greater permeability including geologic faults and down-thrusts, or where rivers have carved channels through the dike formations (Carlquist, 1992; Polhemus, 2007). This process often create conditions where wet grassland occurs. Hawai'i soils can be divided into three broad classes: (a) undeveloped or geomorphologically recent soil substrates, (b) well-developed soils in humid climates, and

(c) well-developed soils in seasonal or dry climates (Mueller-Dombois and Fosberg, 1998). Substrates for Hawai'i wet grassland and shrubland vary from very weathered soils on older islands to rocky substrates on recent lava flows on younger islands.

Physical Characteristics and Vegetation Composition

Native plants of wet grassland and shrubland are long growing and able to recolonize areas after disturbance from stochastic events, but are not able to outcompete many species of invasive plants (Gagné and Cuddihy, 1990). Introduced grasses and shrubs by contrast are disturbance adapted, produce copious numbers of seeds and many introduced grasses spread by rhizomes (underground stems). Because of these characteristics introduced grasses and shrubs rapidly invade disturbed areas of native vegetation and intrude within native plant communities. Hawai'i wet grassland and shrubland is comprised of four community subtypes: native wet sedge and grassland, native wet cliff and ridge crest shrubland, introduced grassland, and introduced evergreen shrubland. At a finer scale, these four subtypes are further differentiated into their constituent plant communities, based on dominant plant species or assemblages of cooccurring species present, and described below.

Native Wet Sedge and Grassland

Eragrostis lowland wet grassland: This plant community occurs below the summit crest of the Ko'olau Mountains on O'ahu, and on Moloka'i. This grassland may consist solely of *Eragrostis variabilis* (kāwelu) on sheer cliffs or on weathered basalt in steep drainages but native shrubs are often interspersed (Gagné and Cuddihy, 1990).

'Uki (Cladium) sedgeland: This plant community is dominated by *Cladium jamaicense* ('uki) and occurs on O'ahu and Hawai'i. Examples of the biome subtype occur within Ka'au Crater, O'ahu, and small occurrences of 'uki sedgeland in Kawai Nui Marsh on O'ahu and Waimanu Valley on Hawai'i. All examples of this community need active management to halt weed invasion (Gagné and Cuddihy, 1990).

Montane wet sedgeland: This plant community is dominated by sedges, including *Carex alligata*, *C. echinata*, *C. montis-eeka*, *Rhynchospora chinensis* (spp. *spiciformis*), and *Oreobolus furcatus*, and occurs both in open boggy areas as well as areas of mixed native-nonnative wet shrubs and grass/sedges in wet cliff and ridge crest areas, and inclusions within forest areas (Gagné and Cuddihy, 1990).

Carex alligata sedgeland occurs as treeless openings in montane wet forests in waterlogged sites and usually have standing water or water table just below the surface. This plant community occurs in wet forest of upper Hāna and upper Kīpahulu Valley in Haleakalā National Park, East Maui, and on Hawai'i in the Kohala Mountains and the Hāmākua region (Gagné and Cuddihy, 1990). Native *Deschampsia australis* (pili) grass occurs in *Carex alligata* sedgeland in high elevation bogs of east Maui (Vogl and Henrickson, 1971).

Carex echinata sedgeland occurs only on Maui in wet forest communities of upper Hāna at 1600–2100 m, on level, poorly drained sites (Gagné and Cuddihy, 1990).

Carex montis-eeka, *Rhynchospora chinensis* (spp. *spiciformis*), and *Oreobolus furcatus sedgeland* occurs in level high elevation bogs on Kaua'i and West Maui.

Native Wet Cliff and Ridge Crest Shrubland

Lowland wet shrubland: This plant community occurs on windswept ridge crests or in gulches on all of the main islands except Ni'ihau and Kaho'olawe at 200–900 m elevation.

Metrosideros polymorpha ('ōhi'a) shrubland occurs at summits and along ridge crests of the Ko'olau Mountains on O'ahu and is dominated by three species of *Metrosideros*: *M. polymorpha*, *M. rugosa* (lehua papa), and *M. tremuloides* (lehua 'āhihi).

Pipturus albidus (māmaki) riparian shrubland occurs in wet gulches on all the main islands except Ni'ihau and Kaho'olawe. Occasionally, this shrubland consists only of māmaki, but more frequently is mixed with other native members of the family Urticaceae such as *Touchardia latifolia* (olonā), *Boehmeria grandis* ('ākōlea), and *Urera glabra* (ōpuhe) (Gagné and Cuddihy, 1990).

Wet cliff and ridge crest shrubland: This community is characterized by different species of native shrubs, including *Dubautia* spp., *Lobelia* spp., *Vaccinium calycinum*, *Dicranopteris linearis* (uluhe) fern, and native sedges and occurs on crests, steep ridges and cliff faces on the islands of Kaua'i, O'ahu, Moloka'i, Maui, and Hawai'i. Annual rainfall is 250–500 cm year (Gagné and Cuddihy, 1990). This environment is characterized by regularly windy and usually foggy and wet conditions. Soils are generally thin over soft, highly weathered rock and thin mucky clays. Vegetation is windswept and variable, ranging from dense dwarf-shrublands to dominant sedges with few scattered shrubs to sparse rock with very little plant life. Wind-stunted trees and shrubs are 1–3 m in height, and are clothed with epiphytic cryptogams (plants which do not bear flowers or seeds) and there is a diverse array of native shrubs, vines, herbs, and ferns. Woody plants are so stunted in some sites that sedges and ferns form a continuous canopy with them. Dominant species vary according to island and terrain. Native species of wet cliff and ridge crest shrubland vary according to island but generally include wind-stunted species of *Metrosideros* ('ōhi'a), *Cibotium* (hapu'u or tree fern), and shrubs, *Melicope*, *Myrsine*, and *Vaccinium*. Other species include *Asplenium* spp. (ferns), *Astelia menziesiana*, *Bidens* spp., *Broussaisia arguta* (kanawao), *Cyrtandra* spp., *Diplopterygium pinnatum*, *Dicranopteris linearis* (uluhe) fern, *Dubautia* spp., *Eurya sandwicensis* (anini), *Freycinetia arborea* ('ie'ie), *Kadua terminalis* (manono), *Lycopodiella cernua* (wāwae'iole or staghorn clubmoss), *Lobelia* spp., *Machaerina angustifolia* ('uki), *Peperomia* spp., *Phyllostegia* spp. (mint), *Scaevola* spp., *Sadleria pallida*, and *S. cyatheoides* ferns ('ama'u), *Tetraplasandra* spp., *Trematolobelia*

spp., and several rare endemic species including the orchid *Anoectochilus sandwicensis* and *Brighamia insignis* (Gagné and Cuddihy, 1990; Landfire, 2016).

Mixed fern shrubland (uluhe ferns and native shrubs) is characterized by substantial land coverage by uluhe fern and native shrubs including *Dubautia* spp., *Lobelia* spp., *Styphelia tameiameia*, and *Trematolobelia* spp. (Gagné and Cuddihy, 1990).

Mixed native-nonnative wet shrubs and grass/sedges include both native species, as above, and invasive grasses and shrubs.

Introduced Wet Grassland

Introduced wet grassland is generally characterized by three species of invasive grasses: *Paspalum conjugatum* (Hilo grass), *Setaria palmifolia* (palm grass), and *Ehrharta stipoides* (meadow rice grass) (Cuddihy and Stone, 1990). These grasses rapidly invade disturbed areas, and form complete ground cover. Depending upon the dominant grass, they can tolerate mesic conditions and moderate shade. Other introduced species of grasses in this biome subtype include *Pennisetum clandestinum* (kikuyu grass), *Digitaria decumbens* (pangola grass), *Panicum maximum* (guinea grass), *Brachiaria mutica* (para grass), and *Cenchrus ciliaris* (buffle grass) (Urata, 1982). These five grasses are desirable forage for cattle and comprise managed pasture areas.

Introduced Evergreen Shrubland

Introduced evergreen shrubland is dominated by two species of invasive shrubs: *Schinus terebinthifolius* (Christmas berry) and *Ulex europaeus* (gorse).

Biome Extent and Range Prior Human Contact

Prior to human contact, Hawai'i wet grassland and shrubland consisted only of native wet sedge and grassland and native wet cliff and ridge crest shrubland, described above. Figs. 1–4 show what is thought to have been the extent of Hawai'i wet grassland and shrubland prior to Polynesian arrival ca. 500 AC (Cuddihy and Stone, 1990).

Biome Extent and Range After Human Contact

Nonnative grasses were introduced to Hawai'i after introduction of cattle in the late 18th and early 19th century, and many of these became invasive (Cuddihy and Stone, 1990). In the late 19th and early 20th century, gorse and Christmas berry were introduced, and quickly invaded native communities (Cuddihy and Stone, 1990). Currently, there are approximately 65,000 ha of wet grassland and shrubland (native and introduced) on the islands of Hawai'i, Kaua'i, Lāna'i, Maui, Moloka'i, and O'ahu (Figs. 5–8). Approximately 48% of wet grassland and shrubland biome today is native species dominated (defined by native species cover > 50%). Fig. 9 shows the relative proportion of vegetation classes of native and introduced wet grassland and shrubland by island.

Native Wet Sedge and Grassland

Within wet montane forest, the native wet sedge and grassland subtype occurs generally in small areas (< 1 to few ha area in size), and limited to areas with poor drainage and soils saturated with water preventing growth of trees and shrubs. Wet sedge and grassland occurs on east Maui and the Alakai Plateau on Kaua'i in large areas often many hectares in size. Areas of native wet sedge and grassland also occur in wet cliff and ridge crest shrubland, and mixed native-nonnative wet shrubs and grass/sedges in wet cliff and ridge crest areas.

Native Wet Cliff and Ridge Crest Shrubland

There are four vegetation communities within the wet cliff and ridge crest shrubland biome subtype, distributed across the islands of Hawai'i, Maui, Moloka'i, Lāna'i, O'ahu, and Kaua'i (Figs. 5–8). These are native wet cliff community; native wet shrubland; mixed fern shrubland; and mixed native-nonnative wet shrubs and grass/sedges (Fig. 9).

Native wet cliff community occurs over approximately 7800 ha on islands of Kaua'i, Moloka'i, Maui, and O'ahu. Extensive areas of native wet cliff community occur on cliff faces of the Ko'olau Mountains on O'ahu and Kaua'i.

Native wet shrubland is characterized by dwarf *Metrosideros polymorpha* ('ōhi'a) trees and native shrubs including *Broussaisia arguta* (kanawao), *Clermontia oblongifolia*, *Eurya sandwicensis*, *Hedyotis terminalis*, *Ilex anomala*, *Cibotium* spp. (hapu'u or tree fern), and various bryophytes (nonvascular land plants including liverworts, hornworts and mosses) (Gagné and Cuddihy, 1990). There is approximately 11,200 ha native wet shrubland on Hawai'i, Maui, Moloka'i, and Lāna'i. Examples of native 'ōhi'a montane wet shrubland occur within the State of Hawai'i Natural Area Reserves on West Maui and The Nature Conservancy, Kamakou Preserve on Moloka'i.

Fig. 1 Historic and current distribution wet grassland and shrubland, Island of Hawai'i.

Mixed fern shrubland (uluhe ferns and native shrubs): There is approximately 9600 ha mixed fern shrubland on the islands of Hawai'i, Maui, and O'ahu. Examples of native mixed fern shrubland occur within Mount Ka'ala Natural Area Reserve on O'ahu, and Kīpahulu Valley, Haleakalā National Park, Maui (Gagné and Cuddihy, 1990).

Mixed native-nonnative wet shrubs and grass/sedges: Approximately 2300 ha of this biome subtype occur on islands of Hawai'i and Moloka'i.

Introduced Wet Grassland

There are approximately 27,000 ha introduced wet grassland distributed across the islands of Hawai'i, Kaua'i, Lana'i, Maui, Moloka'i, and O'ahu (Amidon and Reeves, 2018). Many areas of introduced wet grassland is pasture and occurs in lowland areas (Figs. 5–8). Pasture grass improvement in Hawai'i in the 20th century has occurred largely by introduction of palatable grasses for livestock including *Pennisetum clandestinum* (kikuyu grass), *Digitaria decumbens* (pangola grass), *Panicum maximum* (guinea grass), *Brachiaria mutica* (para grass), and *Cenchrus ciliaris* (buffle grass) (Urata, 1982), and these forage grasses are dominant species of many introduced wet grassland areas.

Fig. 2 Historic and current distribution wet shrubland and grassland, Islands of Moloka'i, Lāna'i, Maui and Kaho'olawe.

Fig. 3 Historic and current distribution wet shrubland and grassland, Island of O'ahu.

Fig. 4 Historic and current distribution wet shrubland and grassland, Islands of Kaua'i and Ni'i'hau.

Introduced Evergreen Shrubland

There are approximately 9000 ha nonnative wet shrubland distributed across the islands of Hawai'i, Kaua'i, Lana'i, Maui, Moloka'i, and O'ahu. This area is dominated by two invasive shrub species: *Schinus terebinthifolius* (Christmas berry) and *Ulex europaeus* (gorse). Both species also occur in mesic and dry areas.

Christmas berry evergreen shrubland: Christmas berry occurs over much of the southern half of the Wai'anae Mountains on O'ahu and is a threat to wet lowland plant communities on Maui and Hawai'i, in Haleakalā and Hawai'i Volcanoes National Parks, and Kalaupapa and Kaloko-Honokohau National Historic Parks (Cuddihy and Stone, 1990). A band of dense Christmas berry shrubland occurs at the lower margin of wet forest on the Kona side of Hawai'i Island.

Gorse evergreen shrubland: Although gorse is dry adapted, major infestations occur in mesic and wet areas adjacent to native forest on the islands of Hawai'i and Maui. Gorse is capable of invading native open upland forests and subalpine shrublands (Cuddihy and Stone, 1990). Gorse in mesic and wet areas covers over 8000 ha on the southeastern slopes of Mauna Kea, from 1981 to 2399 m elevation, and isolated pockets occur in wet forest down to 450 m elevation. Gorse occurs over nearly 6000 ha in mesic and wet areas on the northwestern slopes of Haleakalā, East Maui, between 631 and 2219 m elevation (Cuddihy and Stone, 1990).

Stressors

The health and distribution of Hawai'i native wet grassland and shrubland is affected by natural and nonnative processes and agents, including extreme weather events (hurricanes and tropical storms), climate change, drought, invasive ungulates, loss of plant pollinators, invasive rodents, invasive plants, and development (Table 1). Prior to human contact, native wet grassland and shrubland occurred on most cliffs and ridgelines, as inclusions within wet montane forest with the appropriate soil and hydrologic conditions, and open boggy areas with soil and hydrologic conditions that prevent forest establishment. Based on observation of current biome behavior in response to recent climate conditions, the wet grassland and shrubland biome likely was restricted prior human contact primarily by water availability and weather conditions (drought, tropical storms or hurricanes). After human contact, invasive ungulates and plants degraded native wet grassland and shrubland but these same stressors often benefit introduced wet grassland and shrubland.

Fig. 5 Current distribution wet grassland and shrubland, Island of Hawai'i.

Extreme Weather Events

Hurricanes and tropical storms in the past 100 years have caused substantial damage to wet forest on Kaua'i, Maui and Hawai'i (Harrington et al., 1997; Businger, 1998) and presumably caused damage to wet cliff and ridge crest shrubland. Extended periods of heavy rainfall associated with extreme weather events, and rainfall runoff can cause erosion leading to destabilization of soils and landslides particularly in steep cliff and ridge crest areas, creating opportunities for disturbance adapted invasive grasses and shrubs to colonize eroded areas.

Climate Change and Drought

Effects of climate change on wet grasslands and shrublands include increasing air and ocean temperature and changes in precipitation. Effects of global climate change from the 1950s to 2007 in Hawai'i show an increasing number of consecutive dry days related to increased frequency of El Niño events (Smith and Reynolds, 2004; Chu and Chen, 2005; Giambelluca et al., 2008; Chu et al., 2010). Climate models predict continued drying climate during the wet winter season and dry leeward side of the islands through the 21st century (Timm and Diaz, 2009). Due to decreasing rainfall and increasing temperatures, drying climate has

Fig. 8 Current distribution wet shrubland and grassland, Islands of Kaua'i and Ni'i'hau.

Fig. 9 Wet grasslands and shrublands vegetation summary.

Table 1 Stressors of Hawai'i wet grassland and shrubland by biome sub-type.

Stressor	Native wet grassland	Native wet shrubland	Introduced grassland	Introduced shrubland
Extreme weather events	x	x		
Climate change	x	x		
Drought	x	x		
Invasive ungulates	x	x		
Loss of plant pollinators	x	x		
Invasive rodents	x	x		
Invasive plants	x	x	x	
Development			x	x

contributed to increased drought stress of native plants throughout Hawai'i and increased fire occurrence (Dolling et al., 2005; Giambelluca et al., 2008; Frazier et al., 2012).

Invasive Ungulates

Feral pigs (*Sus scrofa*) and goats (*Copra hircus*) uproot and eat native plants and provide opportunities for disturbance-adapted invasive species to replace them (Gagné and Cuddihy, 1990). Feral pigs, goats, and sheep (*Ovis aries*), where these animals are able to reach cliffs and ridge crests, cause damage to wet cliff and ridge crest shrubland and grassland by consuming native plants, trampling, causing erosion through plant removal and soil compaction and spreading nonnative invasive plant seeds (Pratt and Jacobi, 2009).

Loss of Pollinators

Loss of pollinators is a stressor particularly for rare plant species such as *Brighamia insignis* and *Psychotria grandiflora* (kopiko) on Kaua'i that co-evolved with insect pollinators (Potenza, 2017). Once pollinated by the very rare, fabulous green sphinx moth (*Tinostoma smaragditi*), *P. grandiflora* now must be hand pollination by humans for the plants continued survival.

Invasive Rodents

Rats (black rat (*Rattus rattus*) and Polynesian rat (*Rattus exulans*)) eat the seeds and leaves of native plants in wet cliff and ridge crest shrubland, including kopiko (Potenza, 2017). Mice also eat seeds of Hawaiian plants although it is not known whether mice is a stressor for Hawai'i wet grassland and shrubland biome (Cuddihy and Stone, 1990).

Invasive Plants

The original native flora of Hawai'i (species that were present before humans arrived) consisted of about 1000 taxa, 89% of which were endemic (species that occur only in the Hawaiian Islands). Over 800 plant taxa have been introduced from elsewhere, and nearly 100 of these have become pests (i.e., injurious plants) in Hawai'i (Cuddihy and Stone, 1990; Gagné and Cuddihy, 1990). Of these 100 nonnative pest plant species, close to 70 species have altered native biomes. The most-often cited effects of nonnative plants on native plant species are displacement through competition. Competition may be for water or nutrients, or it may involve allelopathy (chemical inhibition of other plants). Nonnative plants may also displace native species by preventing their reproduction, usually by shading and taking up available sites for seedling establishment (Cuddihy and Stone, 1990). There are a number of invasive plants that out compete and displace native plants of Hawai'i wet grassland and shrubland. The introduced plants below share a number of characteristics. They produce numerous seeds easily and widely dispersed by animals, form dense stands or mats of vegetation, and are difficult to control once established. These species once established are capable of replacing native species of wet grassland and shrubland biome, and in some instances changing native biome to introduced forest.

Psidium cattleianum (strawberry guava): Since its introduction to the Hawaiian Islands in the early 19th century from its native range in Brazil, *Psidium cattleianum* (strawberry guava) has become invasive and has expanded into most of the native lowland forests of Hawai'i, becoming the dominant species in these areas (State of Hawaii, 2011). Strawberry guava regenerates both by seed and root sprouts; is able to regenerate in dense shade; is a prolific fruiter; and its seeds spread both by birds and feral ungulates (State of Hawaii, 2011). On O'ahu, strawberry guava is spreading along ridge crests into 'ōhi'a dominated lowland wet shrubland (Gagné and Cuddihy, 1990).

Clidemia hirta (Koster's curse): *Clidemia hirta* (Koster's curse or Clidemia) occurs in forest areas near wet cliffs, and some wet cliff and ridge crest shrubland (HERP, 1998). *Clidemia* grows between 1 and 5 m tall, depending on habitat, replaces native plants of the forest understory, overtops shorter vegetation and almost nothing can grow beneath its shade (Cuddihy and Stone, 1990; Smith, 1992). The purple-brown to blue-black berries each contains more than 700 tiny seeds that are widely spread by birds. In

undisturbed areas *Clidemia* levels remain low; however once an area is disturbed, colonization proceeds rapidly (Smith, 1992). Moloka'i has an infestation totaling more than 6000 ha, primarily in Wailau and Pelekunu Valleys of the North Shore, with some intrusion in wet cliff and ridge crest areas (Cuddihy and Stone, 1990; HERP, 1998). *Clidemia* is starting to invade the Koke'e/upper Alaka'i area on Kaua'i that abuts areas of native wet cliff shrubland.

Hedychium gardnerianum (Kahili ginger): *Hedychium gardnerianum* (Kahili ginger), and the very similar *H. coronarium* (white ginger) and *H. flavescens* (yellow ginger), are vigorous herbs capable of forming a very dense ground cover that excludes all other growth (Cuddihy and Stone, 1990). Kahili ginger typically achieves heights greater than 1 m and can displace all other understory plants in its vicinity (Cuddihy and Stone, 1990). Major infestations of Kahili ginger occur at Koke'e State Park, Kaua'i, and windward East Maui, and Hawai'i Volcanoes National Park, Hawai'i (Cuddihy and Stone, 1990). This very aggressive plant is able to form dense stands in open areas (forest margins, ravines or path sides) (Djedbour, 2008), and is a serious potential stressor to wet cliff and ridge crest habitat particularly areas on Kaua'i.

Cyathea australis (Australian tree fern): *Cyathea australis* (Australian tree fern) is a recent introduction into Hawai'i planted in private and hotel gardens at low elevations on O'ahu, Maui, and Hawai'i, and naturalized on O'ahu, Kaua'i, Maui, and Hawai'i (Cuddihy and Stone, 1990; Hawaii Invasive Species Council [HISC], 2019a,b, Australian Tree Fern). This large tree fern can grow to 12 m tall and windblown spores travel over 12 km from the parent plant. Fast growing, it aggressively out competes native plants in the forest understory and displaces native ferns including the slower growing hapu'u fern (Hawaii Invasive Species Council [HISC], 2019a,b, Australian Tree Fern). Australian tree fern occurs on Kaua'i in wet cliff areas at Wainiha and Lumahai Valleys (Long, 2007).

Tibouchina herbacea (cane Tibouchina): Native to Brazil, this shrub is semi-woody, can grow up to 3 m tall, a prolific seeder and spread by birds (Hawaii Invasive Species Council [HISC], 2019a,b, Cane Tibouchina). Cane Tibouchina has invaded some high elevation bogs on Maui (Kaiser, 2018).

Development

Ground breaking for development allows introduced grasses and shrubs to invade disturbed areas. Wet cliff and ridge crest habitat is almost entirely inaccessible to development. Development however causes ground disturbance in introduced wet grassland allowing the spread of undesirable grasses and shrubs, and pasture replacement by housing.

Conservation Efforts

Laws and Biosecurity

Protection of relatively intact natural areas and control of the introduction and spread of invasive species is critical for protecting the integrity of native wet grassland and shrubland (Gon and Olson, 2018). Endangered species protections and biosecurity and invasive species laws, regulations, coordination, and authority aid in conservation efforts for native wet grassland and shrubland by preventing introduction of invasive plants and providing legal protections for rare native species (Table 2).

Endangered species act: The Endangered Species Act (ESA) of 1973 aims to provide a framework to conserve and protect endangered and threatened species and their habitats. "Take" under the act has been broadly defined to include "harass, harm, pursue, hunt, shoot, wound, kill, trap, capture or collect." However, there is no take prohibition for plants. The U.S. Fish and Wildlife Service (USFWS) however has determined that "harm" includes "significant habitat modification or degradation" (USFWS, 2013). Thus, the habitat as well as the endangered animal may receive protection. As habitat loss is the primary threat to most imperiled species, the ESA allows the USFWS and National Marine Fisheries Service (NMFS) to designate specific areas as protected "critical habitat" zones. Seventeen percent (10,769 ha) of native wet grassland and shrubland in the state of Hawai'i are designated as critical habitat (Fig. 10) that provides native biome protection.

Biosecurity and invasive species control: A number of federal executive orders and State of Hawai'i conservation initiatives restrict introduction of invasive species to Hawai'i and are the basis of management frameworks for control of invasive species.

Federal executive orders. Executive Order 11987 (1977) requires Federal agencies, to the extent permitted by law to: restrict the introduction of invasive species into the natural ecosystems on lands and waters owned or leased by the United States. Order 11987 also encourages States, local governments, and private citizens to prevent the introduction of invasive species into natural ecosystems of the U.S. and the importation and introduction of invasive species into any natural U.S. ecosystems. Executive Order 13112 (1999) calls upon executive departments and agencies to take steps to prevent the introduction and spread of invasive species, to support efforts to eradicate and control invasive species that are established, and established a National Invasive Species Council (NISC) and the Invasive Species Advisory Committee (ISAC). Executive Order 13751 (2016) expanded the NISC membership, clarified NISC operations, and incorporated additional considerations including health, climate change, and emerging priorities. *State initiatives.* The Hawai'i Invasive Species Council (HISC) is a government body established by the Legislature of the State of Hawai'i with authority to provide funding and establish State policy for invasive species. In January 2017, the HISC adopted Resolution 17-1 endorsing the Hawai'i Interagency Biosecurity Plan and committing to its implementation. Key players in Hawai'i's biosecurity include the Hawai'i Department of Land and Natural Resources (DLNR), Hawai'i Department of Health (DOH), and University of Hawai'i (UH).

Table 2 Laws and regulations benefiting native wet grassland and shrubland subtypes.

<i>Title</i>	<i>Year implemented</i>	<i>Authority</i>	<i>Intent/purpose</i>
Endangered species act	1973	Federal	Protects critically imperiled species from extinction
50 CFR 16	1974	Federal	Implements the Lacey Act (18 USC 42), which prohibits importation of injurious species
Convention on International Trade in Endangered Species	1975	International	Ensures that international trade in specimens of wild animals and plants does not threaten the survival of the species in the wild
Executive order 11987	1977	Federal	Charges executive agencies with restricting the introduction of exotic species into the natural ecosystems on federal lands; and encourages States to do the same
Hawai'i Administrative Rules, title 4, subtitle 6, chapters 68 and 70	1981	Hawai'i (Department of Agriculture, DOA)	Rules/amendments for noxious weeds, plant and nondomestic animal quarantine, plant import, and bromeliad import
Executive order 13112	1999	Federal	Requires that a Council of Departments dealing with invasive species be created to prevent the introduction of invasive species and provide for their control and to minimize the economic, ecological, and human health impacts that invasive species cause
HRS 194-2	2002	Hawai'i (Department of Land and Natural Resources, DLNR)	Establishes Hawaii Invasive Species Council (HISC)
Act 85	2003	Hawai'i (HISC)	Conveys statutory authority to HISC to continue to coordinate approaches among the various State and Federal initiatives for the prevention and control of invasive species
Act 36 (2011) HRS 150A-5.3	2011	Hawai'i (DOA)	Imposes a fee for the inspection, quarantine, and eradication of invasive species contained in any freight brought into the State
HB 1568	2011	Hawai'i (DOA)	Requires commercial harbors and airports in Hawai'i to provide biosecurity and to facilitate cargo inspections
HRS 174C Hawaii State Water Code	2013	Hawai'i (CWRM)	Establishes Commission on Water Resource Management (CWRM) and Water Resource Management Fund
Executive order 13751	2016	Federal	To prevent the introduction of invasive species and provide for their control, and to minimize the economic, plant, animal, ecological, and human health impacts that invasive species cause (amends EO 13112)
7 CFR 360.200	2018	Federal	Designates certain plants as noxious weeds

Stakeholder Engagement

Watershed partnerships: The Hawai'i Association of Watershed Partnerships (HAWP) comprises 10 island-based statewide watershed partnerships that work collaboratively with more than 74 public and private partners on five islands to protect over 890,308 ha of vital forested watershed lands (HAWP, 2018). The HAWP's mission is to increase the effective management and protection of mauka (upper elevation) watershed areas. Watershed partnerships undertaking conservation actions that protect and manage large areas of native wet grassland and shrubland include the East Maui Watershed Partnership, West Maui Watershed Partnership, East Moloka'i Watershed Partnership, Ko'olau Mountains Watershed Partnership, Wai'anae Mountains Watershed Partnership, and Kaua'i Watershed Alliance.

Invasive species councils: The State of Hawai'i created a group of invasive species councils (ISC's) to focus on priority threats identified by island. The invasive species councils are projects of the Pacific Cooperative Studies Unit and the Research Corporation of the University of Hawai'i (UH). The ISC's are voluntary island-based partnerships on Kaua'i (KISC), O'ahu (OISC), Maui (MISC), Moloka'i (MOMISC), and the Big Island (BIISC) (Hawai'i Island) that work with government agencies, nonprofit organizations, and private businesses and landowners to protect each island from the most threatening pests with a proactive approach. Each ISC has a staff that includes a field crew who works across thousands of hectares every year to rapidly respond to and control new invasive pests. The ISC's target species that have high potential to severely impact the economy, environment, agriculture, human health, and

Fig. 10 Wet grasslands and shrublands critical habitat summary.

quality of life. Work done by these councils contributes directly to conservation by removal and reduction of invasive plants and animals in native wet grassland and shrubland areas and other Hawai'i biomes. In addition, the ISC's helps generate awareness and education to the public that in turn enhances this conservation strategy for wet grassland and shrubland biome.

Conservation Areas

Native wet grassland and shrubland occurs within conservation areas on Kaua'i, O'ahu, Moloka'i, Maui, Hawai'i, and Lāna'i. Nine percent (10,769 ha) of native wet grassland and shrubland is protected in reserves, defined as protected areas including national historic parks, national parks, national wildlife refuges, natural areas reserves, private preserve, state wilderness parks, The Nature Conservancy preserves, and wildlife sanctuaries (Reeves and Amidon, 2018).

On Kaua'i, the State of Hawai'i owns and manages the Alaka'i Wilderness Preserve that contains wet cliff and ridge crest shrubland and large areas of montane grassland and sedgeland. On O'ahu, portions of the Mount Ka'ala and Kaluanui Natural Area Reserves (NARs), owned and managed by the State of Hawai'i, contain wet cliff and ridge crest shrubland (HDLNR, 2016). On Moloka'i, wet cliff and ridge crest shrubland and native wet grassland occurs in portions of The Nature Conservancy's 2331 ha Pelekunu, and 1123 ha Kamakou Preserves (The Nature Conservancy of Hawai'i [TNCH], 2018a, 2018b), and the State of Hawai'i Pu'u Ali'i and Oloku'i NARs (Hawaii Department of Land and Natural Resources [HDLNR], 2016). On Maui, native wet grassland and shrubland occurs in Haleakalā National Park (NP), and the State of Hawai'i, West Maui NAR (Hawaii Department of Land and Natural Resources [HDLNR], 2016). On Hawai'i Island, the Pu'u O 'Umi NAR contains some wet cliff and ridge crest shrubland. On Lāna'i, Pūlama Lāna'i Company, is actively moving forward with projects for historical and cultural preservation and natural resource conservation including wet grassland and shrubland areas (Pūlama Lāna'i, 2014).

Conservation Activities

Conservation efforts to prevent degradation of native wet grassland and shrubland consist primarily of fencing and ungulate removal and weed control. These efforts have been effective at protecting and maintaining native wet grassland and shrubland where the biome subtype is minimally invaded by nonnative plants. Management of wet grassland and shrubland in areas already significantly impacted by ungulates and invasive plants has proven more difficult.

Fencing and ungulate control: Many areas of steep wet cliff and ridge crest scrubland are inaccessible to invasive ungulates (pigs, sheep and goats). In areas where ungulates can gain access to this biome subtype, fencing built across ridgelines helps prevent movements of ungulates into native wet grassland and shrubland areas. Ungulate exclusion fencing protects virtually all bog areas of native grasses and sedges (Honoluluadvertiser.com [HNLA], 2008; Kaiser, 2018).

Weed control: Control of invasive plants is ongoing by ISCs, Federal and State agencies and private landowners. Most effective for conservation of native grassland and shrubland is the exclusion of ungulates before substantial damage to native vegetation and introduction of weeds. Once invasive weeds establish in native grassland and shrubland methods available for their control may be inadequate to stem further invasion.

Strawberry guava: Strawberry guava currently occupies over 200,000 ha of lowland forest in Hawai'i (State of Hawaii, 2011). This extremely aggressive invader in areas where it is well established cannot be controlled using mechanical or chemical means. *Tectococcus ovatus* is a highly specific natural control agent producing leaf galls on strawberry guava that reduce its vigor and fruiting (Wikler and Smith, 2002; State of Hawaii, 2011). *T. ovatus* was first released in 2012 on Hawai'i Island in two demonstration plots and gall formation observed (Chaney and Johnson, 2013). It is too early however to know what effect releases of *T. ovatus* may have on strawberry guava on a regional scale.

Clidemia: Mechanical control of *Clidemia* is time consuming and even the leaves of pulled plants may form new roots and reestablish (Smith, 1992). Measures tested for biological control of *Clidemia* appear inadequate to control this species (Conant, 2002).

Kahili ginger: Although a number of diseases and insects are known to attack gingers, most promising for control of Kahili ginger is the bacterium *Ralstonia solanacearum*, which causes widespread plant death 16–20 weeks following inoculation (Anderson and Gardner, 1999). However, herbicidal control methods for ginger are not completely effective and are difficult to implement over large areas (Santos et al., 1986). Mechanical removal of ginger by digging up rhizome masses accomplished in small portions of Hawai'i Volcanoes National Park (HAVO), but this method of control is time consuming and labor intensive (Cuddihy and Stone, 1990).

Australian tree fern: On Kaua'i, Australian tree fern has invaded areas of pristine native forest and wet cliff habitats. Efforts to eradicate this noxious pest by aerial applied, targeted poisoning of individual plants are ongoing. Follow up surveys will indicate whether efforts to contain this pest in wet cliff areas on Kaua'i are effective (Sci-Tech Today, 2007; Borel, 2013).

Palm grass: Hawai'i Department of Forestry and Wildlife foresters on Kaua'i controlled palm grass where it had invaded native forest with drizzle applications of glyphosate at 0.75 lb/acre, but preventing reinvasion required continual monitoring and retreatment until the seed reservoir was exhausted. Hawai'i Volcanoes National Park (HAVO) staff reported control of palm grass in forest areas with foliar application of glyphosate at 1% of product (Motooka et al., 2003a,b, *Setaria palmifolia*).

Meadow rice grass: Glyphosate and imazapyr were used to suppress meadow rice grass at HAVO but with variable success depending upon amount of rainfall following herbicide application (Leary, 2009).

Christmas berry: Some biological controls for Christmas berry have been tried experimentally in Hawai'i but with limited success (Cuddihy and Stone, 1990). Herbicidal treatment or physical removal are the most common measures used to control Christmas berry. Physical removal however may result in greater stem densities if not followed by herbicide treatment to suppress repopulation from seeds in the ground (King, 2002).

Gorse: In 1926, in the 1950s, and beginning in 1984 researchers attempted biological control of gorse in Hawai'i (Markin et al., 1996). Of the more effective biocontrol agents released from 1984 to 1991, *Apion (Exapion) ulicis* (seed-pod-attacking weevil) and *Agonopterix ulicetella* (leaf-eating moth larvae) where successfully established, causing conspicuous damage to plants infected (Markin et al., 1996). Biocontrol for gorse may prevent the infested area from expanding but appears not to eliminate gorse in areas well established (Cuddihy and Stone, 1990).

Conservation of pasturelands: The Natural Resources Conservation Service (NRCS) is the technical agency of the U.S. Department of Agriculture that provides assistance to conservation districts and individuals in planning and carrying out conservation activities (Natural Resources Conservation Service [NRCS], 2018a,b). The NRCS provides financial and technical assistance to address farming and grazing operations concerns including water management, water quality, erosion control and fence management (Natural Resources Conservation Service [NRCS], 2018a,b). NRCS activities have improved pasture quality in introduced wet grassland by planting high quality forage grasses and use of herbicide application for control of invasive grasses. Hilo grass is controlled by introduction of taller forage grasses and grazing, and is sensitive to glyphosate and imazapyr, however both herbicides are nonselective, the latter with some residual soil activity (Motooka et al., 2003, *Paspalum conjugatum*).

Rodent control: Small-scale bait station grids in combination with rat traps have proven successful in reducing and/or eliminating predation on rare plant species by rats on O'ahu in an area containing dry and mesic forest (Mosher et al., 2010). Although rodent control of this scale has not been conducted in native wet grassland and shrubland it is expected it would be beneficial particularly for rare plants that are susceptible to seed predation by rodents.

Prior Human Contact: Redundancy, Resiliency and Representation

Biomes maintain ecosystem function through processes of *redundancy*, *resiliency*, and *representation*. We examine characteristics of redundancy, resiliency, and representation of wet grassland and shrubland prior to human contact and how these may change in the future under different management scenarios.

Redundancy is a biome's ability to withstand a catastrophic event (i.e., hurricanes, landslides, fire, earthquakes, volcanic eruptions, etc.) because multiple distributed communities exist across the landscape (Smith et al., 2018, p. 304). Before human arrival to Hawai'i, native wet grassland and shrubland occupied multiple watersheds on different islands. Because this system was broadly distributed across the island chain, localized catastrophic events, such as landslides, and more broad-scale events, such as landfall by a major hurricane, would not have affected the entire biome. Many of the plant species that comprise native wet grassland and wet cliff and ridge crest shrubland are common on all islands. However, there are plants within the community unique to individual islands. Before human contact, catastrophic events, even quite localized, could have had negative population effects on local species.

Resiliency is a biome's ability to withstand environmental stochasticity (random change in environmental conditions) and related to growth rate and size of species' populations, habitat quality and quantity, and demographic ability of populations to withstand stochastic disturbances (Smith et al., 2018). Before human contact the high species diversity of native wet shrubland would have helped this biome subtype tolerate natural, annual variations in the environment and recover from periodic disturbances (i.e., minor droughts, tropical storms, etc.).

Representation is a biome's ability to adapt to a changing environment over time due to genetic and species diversity and amount of environmental variation within the community type (Smith et al., 2018). Because of its extreme isolation from continental landmasses, species that arrived in Hawai'i were able to fill empty niches not already occupied by other species, which led to speciation (adaptive radiation) and high rate of endemism (Cuddihy and Stone, 1990). Representation prior to human contact however was limited compared to continents due to the few number of ancestral species that colonized the Hawaiian Islands. Environmental variation for native sedges is further limited due to species requirement for standing water or saturated soils.

Current Condition: Redundancy, Resiliency, and Representation

Native Wet Grassland and Shrubland

Native wet grassland and shrubland occupies multiple watersheds on different islands. Because this system is distributed across the island chain, localized catastrophic events, and more broad-scale events, such as landfall by a hurricane, will not affect entire biome, making it redundant. However although many of the plant species that comprise this system are common on all islands, there are rare plants within the community that are unique to individual islands and even watersheds. Therefore, catastrophic events, even quite localized, could seriously effect local species within this community type. Native plants of wet cliffs and ridge crest prior to human contact were resilient and able to recolonize areas after substantial disturbance. Native species are not able to outcompete many species of introduced invasive plants. Once broad areas of strawberry guava, *Clidemia*, Kahili ginger, Australian tree fern and other invasive plants have established, especially in extremely steep and difficult to access terrain, removal of these invasive plants may not be possible and native wet grassland and shrubland become fragmented. Therefore, the community has become less resilient over time.

Introduced Wet Grassland and Shrubland

Introduced wet grassland and shrubland is broadly distributed across the main Hawaiian Islands, making it redundant. This community quickly invades wet forest understory and native wet grassland and shrubland in disturbed areas. Plant species of this biome subtype produce copious numbers of seeds readily dispersed by birds and animals, and form dense stands of monotypic vegetation. The biome subtype responds positively to disturbance factors such as landslides that disrupt native communities, and invasive ungulates promote its establishment and expansion. Because of these characteristics invasive wet grassland and shrubland is strongly resilient. Species of introduced grassland and shrubland occur in mesic and even dry environmental conditions making it well represented due to wide environmental variation.

The Future of Hawai'i Wet Grassland and Shrubland

The condition of Hawai'i wet grassland and shrubland in the foreseeable future will be based on potential changes in conservation management parameters including conservation values, laws and biosecurity, and development or conservation planning. These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out and are critical factors that drive the direction and magnitude of natural resource conservation in the foreseeable future.

Foreseeable Future

The foreseeable future is used in the Endangered Species Act (ESA) as a criterion for determining when a species should be listed as threatened or endangered. The most commonly used factors to establish the "foreseeable future" involve species- or population-specific biological criteria, but also include nonbiological criteria (D'Elia and McCarthy, 2010). For the purposes of the foreseeable future in Biome Status Assessments (BSAs), using species-specific biological criteria will not suffice since the BSAs lack species information and are built upon assessments of ecosystem features that are not typically characterized with reference to specific species (Miller, 2018). As a solution to this unorthodox need, for BSAs the "foreseeable future" is in reference to Global Climate Models (GCMs) developed by the Intergovernmental Panel on Climate Change (IPCC) and other similar assessments. The major uncertainties in climate models are (1) the initial conditions of the climate that are used to set the starting point of the GCMs, (2) the greenhouse gas emission scenario that is used by the model, and (3) the parameterization of important but small-scale and often not-well understood climate processes such as clouds. Uncertainties in what society will do regarding greenhouse gas emissions is the greatest source of variance in the climate predictions. The dotted lines in Fig. 11 highlight the period of estimated least variance in the four climate models (Miller, 2018). Variance increases with increasing years from 2005, the last observed time plotted on the figure. From about 2018 through 2035, the lines for each of the GCM scenarios (RCPs—Representative

Fig. 11 The foreseeable future for global surface warming in reference to Global Climate Models (GCMs).

Concentration Pathways; Van Vuuren et al., 2011a,b) begin to diverge, but prior to 2035 the RCPs remain relatively similar. For the purposes of this BSA, the “foreseeable future” is defined as up to 2035, when the average values of each of the four RCP scenarios do not appear to differ “significantly” in the anticipated amount of global surface warming. The GCMs also provide projections of climate futures to the year 2100 and are downscaled to provide more focused information on the Hawaiian Islands (Table 3).

Conservation Management Parameters

The condition of wet grassland and shrubland biome in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out and are critical factors that drive the direction and magnitude of natural resource conservation in the foreseeable future: *Conservation values* describe stakeholder involvement and public opinion which determine the formulation, implementation and funding of natural resource conservation within laws and development plans. *Laws and biosecurity* encompass national, state, county, and city laws and regulations and are the means by which natural resource conservation and biosecurity are supported and implemented (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.). *Development or conservation planning* encompass national, state, county, city, and private development plans or conservation plans which define specific actions that result in losses or gains in natural resource conservation and biosecurity.

Future Scenarios

We consider four foreseeable future scenarios in this BSA for the CMPs described above:

Future scenario one, status quo: The most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future.

Future scenario two: A slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future scenario three: A slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Future scenario four: A moderate to large increase in conservation actions in the CMPs substantially improves conservation management.

Rates of change in human population for the four future scenarios is captured by the changes in the “developed” land cover footprint derived from land cover map analysis (Amidon and Reeves, 2018). Impacts from other sources of human activities or human-caused habitat stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by nonnative vegetation. Furthermore, island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in

Table 3 Main Hawaiian Islands end-of-century^a and *Foreseeable Future* (2035) projections for select climate indicator variables.

Annual mean climate indicator	Projected change ^a by 2100 (unless noted)	Projected change in 2035 (17 years)
Air temperature	2055: Increase 3.0–3.5 °F (1.67–1.94 °C) 2085: Increase 4.5–5.0 °F (2.5–2.78 °C)	2035: Increase 1.5–2.0 °F (0.83–1.11 °C)
Precipitation ^{a,b}	Decrease 5–10% in wet season Increase 5% in dry season; NWHI: decrease 0–10%	Decrease 1.6–3.2% in wet season Increase 1.6% in dry season NWHI: decrease 0–3.2%
Sea level	Increase 1.48–2.69 ft. (0.45–0.82 m)	Increase 0.47–0.85 ft. (0.14–0.26 m)
Tropical cyclones ^{c,d}	Decrease frequency 4.8% Increased intensity 0.2% Increased duration 2.5% Increase precipitation 20% ^c	Decrease frequency 1.5% Increased intensity 0.06% Increased duration 0.8% Increase precipitation 6.3%

Note: All estimates for 2035 climate conditions in the table were done using linear extrapolations. The climate parameters do not change in a linear manner over time; they follow a concave upward path similar to a power function. Thus, the linear extrapolations will give values that are slightly higher than those obtained from analysis using a convex curved function. This should make any assessment of effects on biomes, ecosystems or federally listed species somewhat conservative and in favor of the biome or species. The four most important impacts (damages) of global climate change in the Pacific Islands are higher air and ocean surface temperatures; changing rain patterns; sea level rise; and ocean acidification.

^dKnutson et al., 2010.

climate response to changes in greenhouse gas emissions that occurs on the order of centuries rather than years (Solomon et al., 2009; Gillett et al., 2011; Jevrejeva et al., 2012). Evidence of climate effects is also confounded by the large annual variation in the Pacific islands climate parameters, which is much greater than projected climate change by 2035. The future condition of wet grassland and shrubland biome in scenario one, status quo, was characterized from an assessment of change over time in wet grassland and shrubland land cover obtained from existing land cover maps (Amidon and Reeves, 2018). Based on these land cover maps, an annual rate of change for wet grassland and shrubland biome was estimated, and a projected change (in hectares) was calculated for the year 2035. The future conditions of wet grassland and shrubland habitat for scenarios two, three, and four cannot be quantitatively estimated. However, the scenario one estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of wet grassland and shrubland under scenarios two, three, and four. A large increase in land cover in pasture (introduced wet grassland) is predicted for Hawai'i Island, but little change in land cover for wet grassland and shrubland biome is predicted for other islands.

Future Scenario One, Status Quo

Summary: Scenario one is considered the most likely future scenario, and serves as a “baseline” for comparing among the four future scenarios. There is no change in the implementation of the three CMPs between 2018 and 2035. Using the current rate of land cover change, a large increase in land cover in pasture is predicted for Hawai'i Island (Amidon and Reeves, 2018). An expanding human population and increased development and general land use on all inhabited islands is anticipated, and therefore biome stressors are expected to increase at a small annual rate. Exceptions are a small to moderate annual rate of increase for development, wild fires, and surface air temperature, and a small annual rate of decrease for precipitation. Development will minimally effect native wet cliff and ridge crest shrubland and sedge and grassland areas because of the steep terrain and remoteness of these biome subtypes from human population areas. Because the scenario one biosecurity CMP remains unchanged while the population and development continue to grow there is an increased potential for new invasive species and new diseases (particularly those affecting native plants). The anticipated changes, under each of the scenarios for stressors important to wet grassland and shrubland biome are in Table 4.

Future Condition

Native wet grassland and shrubland. Native wet grassland and shrubland protected from invasive ungulates and with minimal presence of invasive weeds is expected to continue in its natural state. However, on Kaua'i, where Australian tree fern is well established, there will be continued invasion of this noxious pest in wet cliff and ridge crest areas. Native wet grassland and shrubland is expected to decline in quality in areas where ungulates are present due to ground disturbance, erosion and introduction of invasive plants. For the foreseeable future although reduction in hectares of this native biome subtype is not expected, negative effects of invasive plants in unmanaged areas will continue to occur as will native vegetation decline to a condition where current management tools can no longer prevent transition to biome subtype dominated by invasive species.

Table 4 Responses of wet grassland and shrubland habitat stressors in foreseeable future scenarios.

<i>Conservation management parameters (CMPs)</i>				
Conservation values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans			
Laws and biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented			
Planning for development or conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation)			
Foreseeable future scenarios	and the resulting wet grassland and shrubland habitat conditions			
Use foreseeable future scenario one as a "baseline" to characterize changes in <i>Conservation Actions</i> and <i>Habitat Conditions</i> in future scenarios two, three and four	Scenario one: <i>CMPs</i> : Unchanged in support for NRC/B <i>Conservation actions</i> : No change; current rate of land cover change continues through the foreseeable future <i>Habitat condition</i> : Habitat area, quality, and sustainability slowly decrease through the foreseeable future	Scenario two: <i>CMPs</i> : Small increase in support for NRC/B <i>Conservation Actions</i> : Marginal increase <i>Habitat condition</i> : Habitat area is unchanged through the foreseeable future; habitat quality and sustainability are slightly enhanced through the foreseeable future	Scenario three: <i>CMPs</i> : Small to moderate decrease in support for NRC/B <i>Conservation actions</i> : Substantial decrease <i>Habitat condition</i> : Urban and agricultural uses are prioritized over conservation; habitat area, quality, and sustainability substantially decrease through the foreseeable future	Scenario four: <i>CMPs</i> : Moderate to large increase in support for NRC/B <i>Conservation actions</i> : Substantial increase <i>Habitat condition</i> : Robust, sustained effort to restore, manage, and expand conservation; habitat area, quality, and sustainability substantially increase through the foreseeable future
Habitat stressors	Responses of wet grassland and shrubland habitat stressors			
Invasive ungulates	Small increase	No change	Moderate to large increase	Moderate decrease
Loss of plant pollinators	Small increase	No change to small increase	Moderate to large	Small to moderate decrease
Invasive rodents	Small increase	No change to small increase	Small to moderate increase	Small to moderate decrease
Extreme weather events	Small increase	Small increase	Small to moderate increase	Small increase
Invasive plants	Small increase	Small increase	Moderate to large increase	Small to moderate decrease
Drought	Small increase	Small increase	Small increase	Small increase
Development	Small increase	Small increase	Small to moderate increase	Small to moderate decrease
Erosion	Small increase	No change	Moderate to large increase	Moderate to large decrease
<i>Climate</i>				
Temperature	No change to small increase	No change to small increase	No change to small increase	No change to small increase
Precipitation	Small increase	Small increase	Small increase	Small increase

Introduced wet grassland. Current levels of funding, conservation protections, and methods for control of introduced wet grasses is expected to prevent the further spread of invasive wet grasses in managed native wet forest and wet grassland and shrubland. In unmanaged native biomes there will be no change in the current trajectory for introduced wet grassland's continued expansion in land area covered. Pasture grasses, including kikuyu grass, pangola grass, guinea grass, para grass, and buffle grass are expected to expand in area (Amidon and Reeves, 2018).

Introduced evergreen shrubland. Maintained levels of funding and current methods of weed control will continue to contain populations of introduced evergreen shrubland in areas currently managed. Unmanaged areas of introduced evergreen shrubland will expand in native wet forest. Of concern is the continued spread of Christmas berry by birds. The current effort to detect and remove incipient populations of Christmas berry from wet forest will be inadequate to prevent the establishment of new populations of this noxious shrub in intact wet forest communities. Control of gorse infestations adjacent to conservation areas at Hakalau Forest NWR and Haleakalā National Park will limit gorse from spreading further in these conservation areas.

Future Scenario Two

Summary: Conservation agencies and stakeholders work with increased but limited resources to slow or stop the degradation of native biomes. Scenario two is essentially "status quo" with minor improvements in the three CMPs. Though there is an expanding human population in scenario two, development is not expected to substantially increase. A slightly improved biosecurity effort should help reduce invasive species and plant diseases. The small increased support of natural resource management in the CMPs is not expected to greatly alter the rate of invasive species expansion, however this might lower it slightly compared to scenario one. The CMP supported conservation will not prevent, mitigate, or reverse the impacts of climate change-related stressors.

Future Condition

Native wet grassland and shrubland. With slightly improved conservation values, and laws and planning for development, somewhat greater funding will be available to manage invasive plants in native wet grassland and shrubland. Land managers will be able to prevent the decline of this biome subtype in managed areas by control of incipient populations of invasive plants. Continued decline of this biome subtype will occur in unmanaged areas. For the foreseeable future there will be little or no reduction in hectares of native wet grassland and shrubland however unmanaged areas will transition to a biome sub-type dominated by invasive species.

Introduced wet grassland. Somewhat greater funding will be available for control of invasive grasses, but because of the number of infestations throughout native wet forest and wet grassland and shrubland only a few additional high priority areas will be managed. Introduced wet grassland will expand in native wet forest and native wet grassland and shrubland biomes in unmanaged areas. With slightly improved conservation values, improved effort to remove unpalatable invasive grasses will allow more desirable range grasses to establish in pasture areas.

Introduced evergreen shrubland. Somewhat greater funding will be available for control of Christmas berry and gorse and improved pasture conditions will result. For large areas of these invasive shrubs, funding will be adequate only to prevent the continued expansion of established populations in native biomes. Slightly improved conservation funding will allow improved efforts to search and remove incipient populations of invasive shrubs in some areas of native wet forest and wet grassland and shrubland.

Future Scenario Three

Summary: All natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in protected areas where land development is not possible. Scenario three has substantial declines in natural resource conservation within the three CMPs. An increasing human population is supported in its use of land for economic development over the conservation of native biomes. Areas that cannot support development become the only areas of free-living native species. An expanding human population requires increased land use for agriculture and development with no encumbrance from natural resource management. Biosecurity controls are significantly weakened in this scenario leading to an increase in invasive species problems and new plant diseases. The substantial loss of CMP supported conservation may locally aggravate the impacts of climate change-related stressors of drought and extreme weather events in areas with increased invasive ungulates impacts.

Future Condition

Native wet grassland and shrubland. Under this scenario areas of native wet grassland and shrubland where ungulate fencing is needed to prevent erosion and weed invasion will suffer loss in quantity and quality due to a lack of fence maintenance and reduced effort to control invasive plants. Only the most remote wet cliff and ridge crest areas, impossible to access by invasive ungulates and with little or no invasive plants is likely to continue in its native condition. The reduction in effort to limit the introduction of invasive species to Hawai'i will lead to new invasive introductions, some likely harmful to this biome subtype. Compared to scenario one, more rapid decline in this biome subtype will occur due to increased effects of invasive ungulates and plants. There will be reduction in area of native wet grassland and shrubland as already moderately invaded areas transition to landscapes dominated by invasive species.

Introduced wet grassland. We expect Hilo grass, palm grass, and meadow rice grass to increase in pasture areas due to declines in funding for control of these introduced grasses. Increased development may result in loss of some pasture areas as housing development replaces agricultural lands. Declines in the three conservation management parameters will limit control of invasive grasses to only a few highest value conservation areas. Nonnative grasses will invade previously unaffected native wet forest and native wet grassland and shrubland.

Introduced evergreen shrubland. Areas of well-established evergreen shrubland will expand in size and invade adjacent wet forest and wet pasture. Gorse and Christmas berry, dispersed by water or carried by animals, will establish new populations in native biomes. Compared to scenario one, these effects will result in more rapid expansion of invasive shrubland in native forest and wet grassland and shrubland.

Future Scenario Four

Summary: An overt and robust, active, ongoing effort is made to engage partners and stakeholders in identifying and prioritizing landscape areas needed for the conservation of native biomes and to actively restore and expand these biomes. A substantial emphasis on natural resource conservation is present in the three CMPs, reflecting increased societal concern for declines in natural habitats and biodiversity. Active and well-supported natural resource management begins to restore ecosystems and expand their landscape areas. The needs of an expanding human population are addressed through more efficient land use governance based on redevelopment rather than development of undeveloped areas. Modern and novel agricultural practices focus on those that do not affect existing natural areas or areas needed for native biome restoration. Substantially improved biosecurity regulations decrease introductions of invasive species and plant diseases. The substantial increase in CMP supported conservation may locally mitigate the effects of climate change-related stressors, but climate change is expected to continue.

Future Condition

Native wet grassland and shrubland. With large increase in conservation management parameters, expected greater funding will allow increased management of invasive plants in native wet grassland and shrubland. This will reverse the degradation of areas of this biome subtype moderately affected by introduced plants. Remaining areas of this community will be fenced, protecting all areas of native communities from damage by invasive ungulates. With higher societal value of native species and ecosystems, there will be more acceptance of landscape-level removal of invasive species using traditional and new removal methods. Compared to scenario one, biome subtype resiliency will improve due to lower rates of intrusion and biome fragmentation by invasive species.

Introduced wet grassland. Increased funding for repeated treatments of invasive wet grassland with herbicide will reduce the area of this biome subtype in native forest and wet grassland and shrubland. Research may target development of more effective control measures for invasive grasses (such as biocontrol).

Introduced wet shrubland. Greater funding to control invasive Christmas berry and gorse adjacent natural areas and prevent new population establishment will reduce the area of this biome subtype. More research will target development of effective control measures including biocontrol. With higher societal value of native species and ecosystems there will be more acceptance of landscape-level removals of invasive species including introduced evergreen shrubland using traditional and new removal methods. Pasture quality will improve due to increased effort to remove Christmas berry and gorse.

Conclusion

Native Hawai'i wet grassland and shrubland biome since human contact has become less resilient primarily due to effects of invasive ungulates and invasive plants. Conservation measures to protect the native wet grassland and shrubland biome are effective in areas where ungulates are excluded and few invasive plants are present. However, some invasive plants, particularly strawberry guava and Australian tree fern, are able to spread into even protected and extremely remote areas of native wet cliff and ridge crest grassland and shrubland. Given current levels of conservation management, remote areas of native wet grassland and shrubland are likely to maintain redundancy, resiliency, and representation. Areas of moderately invaded native wet grassland and shrubland however are likely to experience gradual decline in ecological function and resiliency. Introduced wet grassland and shrubland by contrast is likely to expand in area under current levels of conservation management. Substantially improved conservation management will improve native biome resiliency due reduced biome fragmentation by invasive species and improve pasture areas through control of invasive grasses and shrubs.

Abstract

This article provides an overview of the Hawaiian islands mesic grasslands and shrublands, including current status, stressors, and future viability. The mesic grassland and shrubland biome in Hawai'i receives between 1200 and 2500 mm of rainfall each year. It exists on both windward and leeward slopes of the main Hawaiian islands, and is found in both lowland and montane-subalpine zones (Gagne and Cuddihy, 1999). The lowland and montane mesic zones vary by elevation and climate which influences the composition of species within each of the mesic grassland and shrubland ecotypes (Gagne and Cuddihy, 1999). Mesic grasslands and shrublands were distributed across all of the main Hawaiian islands historically, with the majority occurring on the islands of Hawai'i and Maui. This biome is still found on all of the main Hawaiian islands however it is now composed of a mixture of both native and non-native grassland and shrubland ecotypes. Current ecotypes include, the native lowland and montane-subalpine mesic grasslands and shrublands, and three introduced ecotypes: perennial grasslands, evergreen shrublands and deciduous shrublands. Stressors to the mesic grasslands and shrublands are introduced weeds and ungulates, fire, natural disasters (i.e., hurricanes), climate (i.e., drought), plant diseases, and human development/agriculture. Ongoing conservation efforts are helping to protect the mesic grassland and shrubland biome in Hawai'i and depend on the combined efforts of the state and federal government, private landowners, and non-profit organizations. Management efforts are primarily focused on the removal of invasive species (weeds and ungulates) and protection of native grasslands and shrublands through the construction of fenced conservation areas. Our assessment of mesic grassland and shrubland viability is based on the likelihood of persistence over the long term, using the ecological concepts of representation, redundancy, and resiliency. We have evaluated the condition of the mesic grassland and shrubland biome in the foreseeable future (to year 2035) based on different scenarios involving the conservation management parameters of funding and public support for conservation management activities; conservation and biosecurity-related laws; and state/civic planning for conservation planning and land use and development.

Introduction

The Hawaiian archipelago includes eight large volcanic islands (Hawai'i, Maui, Lāna'i, Moloka'i, Kaho'olawe, O'ahu, Kaua'i, and Ni'ihau), as well as numerous offshore islets, shoals, and atolls set on submerged volcanic remnants at the northwest end of the island chain. The archipelago covers a land area of about 16,600 square kilometers (km) with the youngest and largest islands, Maui and Hawai'i, located in the southeast portion of the archipelago. Maui and Hawai'i are both unweathered shield volcanoes and contain the largest amount of land area in the main islands. The island of Hawai'i is still volcanically active. The older "main" Hawaiian islands (i.e., Moloka'i, Lāna'i, O'ahu, Kaua'i and Ni'ihau) are generally more heavily weathered, with steep cliffs and valleys, well developed streams, and gently sloped flood plains ([Gagne and Cuddihy, 1999](#); [Wagner et al., 1999](#)). The geography, geology, climate, hydrology and descriptions of the islands in the Hawaiian archipelago are described in the article on the Physical Geography of the Hawaiian islands by included in this work.

This article provides an overview of the mesic grassland and shrubland biome in the Hawaiian archipelago and describes the ecological factors that have influenced this biome over time and into the future.

Description

A grassland and shrubland is a plant community characterized by vegetation dominated by shrubs and grasses between 1 and 3 meters (m) in height. The classification of Hawaiian mesic grassland and shrubland is based on elevation, moisture, and physiognomy (look, aspect, and appearance). Physiognomic classes of mesic grassland and shrubland are based on percentage of cover of the dominant plant life and include subsets of native and introduced categories. The mesic zone of vegetation in the Hawaiian islands is defined as having an annual precipitation range from 1200 to 2500 millimeters (mm) per year ([Gagne and Cuddihy, 1999](#)). Mesic grassland and shrubland ecosystems are found in the mesic seasonal zone between the dry leeward and wet windward climates. Water availability is a critical component of the mesic grassland and shrubland biome. This biome exists where environmental conditions are less conducive to mesic forests due to shallower soils and more wind exposure ([Wagner et al., 1990](#)).

Mesic grasslands and shrublands occur on most of the main Hawaiian islands including Hawai'i, Moloka'i, Maui, Kaua'i, O'ahu, and Lāna'i on slopes ranging from 30 to 2300 m in elevation. They are found in the mesic seasonal zone between the dry leeward and wet windward climates and average 1000–2500 mm of rainfall annually ([Cuddihy and Stone, 1990](#)). These sites experience precipitation throughout the year but receive most rainfall during the winter months ([Landfire, 2016](#); [The Nature Conservancy \(TNC\), 2006](#)).

This biome is comprised of four native and three introduced plant communities: lowland mesic shrubland, subalpine mesic Shrubland, montane-subalpine mesic grassland, lowland mesic grassland, introduced perennial grassland, introduced deciduous shrubland, and introduced evergreen shrubland.

Biodiversity

Biological diversity is moderate in the mesic grassland and shrubland system relative to lower elevation systems ([The Nature Conservancy \(TNC\), 2006](#)). The lack of trees results in few microclimates created by this ecotype, however, there are several species of grass and shrubs that dominate or co-dominate in areas where this biome is found creating a moderate level of diversity.

Physical/Life History Components

Geological substrates are highly variable for this biome, but soils are generally shallow and often dry out regularly and may contain many rock outcrops ([Landfire, 2016](#)). The soils of mesic shrublands are much rockier than those of the mesic grasslands, and are generally much thinner than those of mesic forests ([Gagne and Cuddihy, 1999](#)).

Development of mesic grasslands and shrublands is influenced by numerous factors including disturbance (fires, volcanism, storms, pathogens, insect pests) as well as by precipitation, light, substrate, and soil availability. These ecotypes (sub-types) generally occur where forests cannot develop (due to a stressor limitation on tree growth), such as along gulch ledges, cliffs, ridges, or where there is regular exposure to strong winds on windward aspects ([Gagne and Cuddihy, 1999](#)).

Natural recruitment in the mesic grassland and shrublands is also driven by dispersal, pollination, and nutrient availability. Forest birds and the Hawaiian goose (Nēnē; *Branta sandvicensis*) provide a vital role in seed dispersal, allowing mesic grasslands and shrublands to maintain and establish in new areas ([Culliney et al., 2012](#)). Native invertebrates also serve an important role in the pollination of native plant species found in the native-dominated mesic grasslands and shrublands ([Magnacca, 2007](#)). Seabirds contribute an important source of marine derived nitrogen to the mesic shrublands through deposition of guano at their nesting sites ([Rowe et al., 2017](#)).

Vegetation Structure and Composition

Vegetation structure and composition varies among the seven subcategories included in the mesic grassland and shrubland category. It may consist of a closed-canopy ecotype dominated by ferns and small shrubs or an open grassland dominated by bunch grasses.

Water availability

Rainfall influences the availability of water for plants and is a critical component of mesic grasslands and shrublands. Shrubs and grasses typically found in mesic grasslands and shrublands require moist conditions throughout the year. Changes in the rainfall and water availability regime can lead to drier or wetter conditions that are not suitable to plants typically found in the mesic grassland and shrubland system. If water availability changes substantially, the area may no longer be favorable for mesic grassland and shrubland plants that prefer a moist environment, and the altered biome may shift to a drier or wetter biome classification if the species shift is substantial.

Viability of Mesic Grasslands and Shrublands (Redundancy, Resiliency, Representation)

The viability of Hawaiian mesic grasslands and shrublands depends on maintaining multiple and distributed populations (redundancy) of sufficient quality and size (resiliency) with species richness and genetic range (representation) to persist over time. We define redundancy by the number, distribution, and connectivity of subunits that make up a biome. By resiliency we refer to the overall health, stability, quality and quantity of subunits that compose a biome. We define representation, by the range of variation that exists within subunits that make up a biome, including environmental conditions and features (geographic, ecological, climatic).

Redundancy

The adequate distribution across the landscape of mesic grasslands and shrublands contributes to its ability to perpetuate after a catastrophic event in one area by having a redundant population in another area. Originally the mesic grass and shrubland communities were present on multiple islands and across multiple watersheds. They were found on both windward and leeward slopes and across a broad range of substrates from the oldest on the island of Kaua'i to the youngest on Hawai'i. Because of this redundancy in the mesic shrub and grassland biome, it is likely that natural catastrophic events such as large fires or hurricanes did not severely impact mesic grasslands and shrublands prior to human contact.

Resiliency

The quality and quantity of mesic grasslands and shrublands contributes to its resiliency in the face of stochastic events. Most native species in this biome are not specifically fire-adapted, however, many species regenerate after disturbance if environmental conditions are optimal. Fire can reset the successional clock of this system by removing a substantial amount of plants. Some seeds will survive and be able to germinate following the fire while others rely on dispersal from sources such as the wind or animals. It is reasonable to expect that mesic grasslands and shrublands were resilient prior to human contact having multiple, large, high quality areas composed of many ecotypes across the biome in the Hawaiian islands.

Representation

Diversity within and among locations of mesic grasslands and shrublands is necessary to enhance its ability to adapt to change. Mesic grasslands and shrublands are best represented when there is geographic and genetic diversity across the range. Representation considerations for this biome include presence on each of the main Hawaiian islands spanning across both leeward and windward slopes, and from lowland to montane elevations. Mesic grassland and shrubland communities prior to humans would have primarily been as inclusions in more tree dominated ecotypes, with limited species richness depending on the community (see discussion below on subtypes) (Cuddihy and Stone, 1990). Limited species richness in the native grassland and shrubland ecotypes may have reduced representation in the pre-human subtypes, making them less viable under changing conditions.

Pre-Human Condition

The original vegetation cover of the Hawaiian islands prior to the arrival of the Polynesians may be inferred from existing vegetation, remnants in disturbed areas, patterns of climate and substrates, and a few fossilized remains (Cuddihy and Stone, 1990). Because of the archipelago's historical isolation, the original vegetation has been characterized as biogeographically impoverished but secondarily enriched by evolution (Mueller-Dombois, 1992). Natural disturbances that shaped vegetation communities in pre-human Hawai'i included volcanic activity, hurricanes, lightning fires, and landslides (Mueller-Dombois, 1992).

Native mesic grasslands and shrublands present in pre-human times include four ecotypes: lowland mesic shrubland, subalpine mesic shrubland, montane-subalpine mesic grassland, and lowland mesic grassland. Dominant species found in pre-human mesic grasslands and shrublands are described in Table 1. These grassland and shrubland communities extended from the lowlands to the subalpine regions and were found on both the leeward and windward sides of the main Hawaiian islands (Cuddihy and Stone, 1990). They were found primarily on the islands of O'ahu, Maui, Kaua'i, and Hawai'i and to a lesser extent on Moloka'i and Lāna'i and were not known from the northwestern Hawaiian islands where vegetation communities are limited to lowland dry and coastal ecotypes (Cuddihy and Stone, 1990).

Prior to human contact the mesic grasslands and shrublands occurred as inclusions within mesic forests and encompassed an area up to 734,086 ac (297,074 ha) as indicated (cross-hatched) in Figs. 1–4. It is likely that shrublands and forests were found together throughout the lowlands, and even extended into coastal areas (Cuddihy and Stone, 1990). The montane grasslands

<i>Tetramolopium lepidotum</i>			

are not believed to have been an important element in pre-human Hawai'i but the lowland kāwelu (*Eragrostis variabilis*) grasslands are thought to have been much more extensive (Cuddihy and Stone, 1990).

Although mesic grasslands and shrublands were found historically on all of the main Hawaiian islands, the majority occurred on the islands of Hawai'i and Maui, with Maui having the highest percentage of grasslands and shrublands represented (Reeves and Amidon, 2018).

Current Condition

Biome subtypes

Mesic grasslands and shrublands currently include four native and three introduced subtypes. Characteristics of these subtypes are described in Table 2.

Hawai'i lowland mesic shrubland

The Hawai'i lowland mesic shrublands are present on all of the main Hawaiian islands except Kaho'olawe. The remaining native lowland mesic shrublands include five sub-types: 'Ōhi'a (*Metrosideros*) Shrubland, Pūkiawe/'A'ali'i (*Leptecophylla/Dodonaea*) Shrubland, 'Ūlei (*Osteomeles*) Shrubland, Nehe (*Lipochaeta*) Shrubland, and Iliau (*Wilkesia* spp.) Shrubland (Gagne and Cuddihy, 1999). These shrublands occupy areas where forests cannot develop, such as along gulch ledges and on cliffs, ridges, and steep slopes, or where there is regular exposure to strong winds on windward aspects. The soils where this sub-type is found are generally shallow and easily dried out. These communities have open or closed canopies with little or no herbaceous layer development. Disturbance and displacement of the native communities has been greatest in the lowlands, leaving remnant native ecotypes at higher elevations or on ridgelines and cliff faces (Gagne and Cuddihy, 1999; The Nature Conservancy (TNC), 2006). In these areas the lowland mesic shrublands are often bounded below by dry or mesic forests, shrublands, or grasslands and above by 'ōhi'a/uluhe (*Metrosideros/Dicranopteris*) fern forest. An exception is the 'ūlei shrubland, which abruptly changes into 'ōhi'a lowland mesic shrubland and kāwelu (*Eragrostis*) lowland mesic grassland (Gagne and Cuddihy, 1999).

In some areas, lowland mesic shrublands are now surrounded by nonnative-dominated shrublands and forests that include Christmas berry (*Schinus terebinthifolius*), java plum (*Syzygium cumini*), and common guava (*Psidium* spp.) (Gagne and Cuddihy, 1999).

Hawai'i subalpine mesic shrubland

This community is represented by a single native ecotype on east Maui, the Ama'u/'Ōhelo (*Sadleria/Vaccinium*) Shrubland (Gagne and Cuddihy, 1999). This shrubland is known from the windward slopes of east Maui and within the adjacent Haleakalā Crater, primarily on ridges and upper slopes of rough, heavily dissected terrain. The substrate is composed of a thin soil with many rock outcroppings. Few herbs are present, but several species of ferns and mosses occur, and epiphytic lichens and bryophytes are abundant. At its lower elevational limits, this dense shrubland is two layered, with 'ōhelo (*Vaccinium* spp.) occurring above a layer of 'ama'u fern (*Sadleria*) and mixed shrubs. On the higher slopes and ridges, the shrubland layer is lower statured, dense, and single layered, with other *Vaccinium* spp. increasing in cover (Gagne and Cuddihy, 1999). Subalpine mesic shrubland is contained almost entirely within Haleakalā National Park or in preserves managed by The Nature Conservancy (Gagne and Cuddihy, 1999). Feral pigs and goats are the primary source of disturbance in the subalpine mesic shrublands. Invasive plants colonize disturbed areas and become established as a result of these animals (Gagne and Cuddihy, 1999). On the Nature Conservancy's Waikamoi preserve blackberry (*Rubus argutus*) and non-native grasses occur in disturbed areas adjacent to this subtype.

Hawai'i montane-subalpine mesic grassland

The Hawai'i montane-subalpine mesic grassland is represented by a single native community, the *Deschampsia* grassland. It is known from both the northeastern slopes of east Maui and on Mauna Loa volcano on the island of Hawai'i. On Maui, it occurs where the soil is thin with very little exposed rock surface. On Hawai'i, the substrate is a shallow ash soil over pāhoehoe. *Deschampsia* grasslands attain a very dense ground cover. Other native plants found in this community include rushes, sedges, and shrubs. On Maui,

Fig. 1 Historical and current extent of the mesic grassland and shrubland system on the island of Hawai'i. Reeves, M.K. and Amidon, F. (2018). Habitat Status Assessment Methods—Hawaii, Current Condition Summaries. August 2018. Technical Report from United States Fish and Wildlife Service, Pacific Islands Fish and Wildlife Office, Honolulu, HI. 439 pp.

the community is bordered downslope by shallow gullies in which the vegetation is dominated by Ama'u/'Ōhelo (*Sadleria/Vaccinium*) Shrubland. *Deschampsia* grassland is also ecotonal below to treeline 'ōhi'a (*Metrosideros polymorpha*) forest on the slopes of Haleakalā. On Hawai'i, sites supporting this community are relatively small and often surrounded by open 'ōhi'a forest (Gagne and Cuddihy, 1999). *Deschampsia* grassland occurs primarily on state and federal lands. A good example is found inside Haleakalā National Park on Maui where over half of the remaining *Deschampsia* grassland in the state occurs. Feral pigs are the primary source

Fig. 2 Historical and current extent of the mesic grassland and shrubland system on the islands of Kaua'i and Ni'ihau.

of disturbance in the subalpine mesic grasslands. Invasive plants colonize disturbed areas and become established as a result of these animals (Gagne and Cuddihy, 1999).

Hawai'i lowland mesic grassland

Most of the vegetation in the lowland mesic shrublands and forests of the main Hawaiian islands has been changed from its original composition and is now composed mainly of mesic grasslands (Mueller-Dombois, 1992) that are floristically poor (Landfire, 2016) and may have originated from human-induced disturbance to the landscape. Native grassland communities generally remain only in areas that were unsuitable for agriculture and other habitat modifying activities by humans (Gagne and Cuddihy, 1999). Currently, there is one native lowland mesic grassland ecotype and two that are dominated by introduced species. The native Kāwelu grassland still exists on the islands of Kaua'i, O'ahu, Moloka'i, and Maui. It is dominated by *Eragrostis variabilis* and is located on moderate to steep slopes where it forms a continuous, dense ground cover. This mesic grassland subtype transitions into lowland mesic shrublands and forests, where 'ōhi'a (*Metrosideros polymorpha*) is present. The community may also extend downslope to coastal dry slopes (Gagne and Cuddihy, 1999). The Kāwelu grassland community is believed to have been much more extensive prior to human arrival (Cuddihy and Stone, 1990).

The introduced ecotypes include the Molasses grasslands (*Melinis minutiflora*) and Beardgrass grasslands (*Andropogon virginicus*/*Schizachyrium condensatum*). These communities have formed in areas that were once native grasslands and shrublands but that have since been disturbed by human activity, invasion by non-native weeds and browsing ungulates, and fire (Gagne and Cuddihy, 1999). Increased frequency of fire in the introduced grassland ecotypes is a result of the fire resilient, mat forming nature of the grass species that compose both ecotypes.

Hawai'i introduced perennial grassland

Introduced perennial grasslands have developed in areas that were once native dominated by lowland grasslands and shrublands but have since been replaced by introduced communities due to human activity. They are dominated by tall, medium, and/or a short statured herbaceous layer. Ecological changes to the community are primarily a result of introduced fire-adapted grasses and long term disturbance by browsing ungulates. The increased frequency of fire in the introduced perennial grasslands has led to the development of homogenous fire climax grass communities in some areas from coastal to subalpine environments (Gagne and Cuddihy,

Fig. 3 Historical and current extent of the mesic grassland and shrubland system on the islands of Moloka'i, Lāna'i, Maui and Kaho'olawe.

1999). This community appears to be in secondary succession and requires continual disturbance for its maintenance (Gagne and Cuddihy, 1999).

Mesic pasture is distributed across 171,696 ac (69,483 ha) in the main Hawaiian islands. The largest proportion of mesic pasture exists on the islands of Hawai'i (59,097 ac; 23,916 ha) and Maui (8145 ac; 3296 ha) (NOAA, 2018). Many areas of pastureland occur within the introduced perennial grassland ecotype because the rainfall regime is optimal for growth of introduced pasture grasses.

Hawai'i introduced deciduous shrubland

The introduced deciduous shrubland cover type is dominated by haole koa (*Leucaena leucocephala*) and other introduced trees and shrubs. Haole koa are highly adaptable but prefer the mesic soil in low elevations. They are drought tolerant, fast growing, and produce a large amount of seeds forming dense thickets (Wildlife of Hawai'i, 2018). The introduced deciduous shrubland community overlaps in range with what was considered lowland mesic forests or lowland shrub and grassland communities historically. This ecotype often occurs throughout the main islands, especially on abandoned grazing lands (Gagne and Cuddihy, 1999). It has developed as a result of browsing by introduced goats and cattle and by processes driven by the increased frequency of fire due to introduced fire adapted grasses (Gagne and Cuddihy, 1999).

Hawai'i introduced evergreen shrubland

The Hawai'i introduced evergreen shrubland is dominated by introduced shrubs including Christmas berry (*Schinus terebinthifolius*) and gorse (*Ulex europaeus*). Christmas berry is fire resistant, drought tolerant, and flood tolerant, and can prevent or inhibit the growth of other plants by releasing chemicals (MISC, 2018). Gorse is a thorny shrub that is present on all of the main Hawaiian islands. It forms dense thickets which completely inhibits the regeneration of native species (USFWS, 2010). Seeds of gorse are adapted to germination after fires and the deep roots of this species make it resilient to fires (DLNR, 2018). In areas where the native vegetation no longer exists in lowland mesic grasslands, and fires have been curtailed, grasslands appear to be successional to shrublands dominated by introduced species such as Christmas berry (Gagne and Cuddihy, 1999). This community has replaced the native-dominated mesic lowland and montane forest, and native mesic shrublands and grasslands, as these native plant communities converted into an introduced shrubland following the introduction of fire tolerant shrub and grass species and as a result of disturbance by introduced ungulates and fire.

Fig. 4 Historical and current extent of the mesic grassland and shrubland system on the island of O'ahu.

Current distribution

Mesic grasslands and shrublands are found across multiple watersheds on all of the main Hawaiian islands. Between approximately 400 and 1800 CE, Hawaiians settled, colonized, and reshaped much of the vegetation of the lowlands, including mesic communities, on all the major Hawaiian islands (Kirch, 1982). In these ecosystems, Hawaiians used fire to clear land for agriculture (i.e., slash and burn). By the time of European contact in the late 1700s, most of the native mesic communities below 2500 ft (760 m) had been converted from forest, woodlands, and shrublands to open grasslands (Cuddihy and Stone, 1990; Kirch, 1982).

Since that time, native lowland mesic communities, including grasslands and shrublands, have been further converted to pasture, military or agricultural use, or have been lost to urbanization or fire (Cuddihy and Stone, 1990; State DLNR, 2016). It is estimated that <10% of the original native vegetation in lowland areas of the main Hawaiian islands currently remains (State DLNR, 2016). The majority of remaining native mesic grasslands and shrublands are found today at higher elevations and in areas where development, agriculture, and grazing have not been as intensive (Cuddihy and Stone, 1990; Figs. 5–8).

There are currently 457,929 ac (185,317 ha) of native and introduced mesic grasslands and shrublands distributed across Hawai'i, Moloka'i, Maui, O'ahu, Kaua'i, Lāna'i, and Ni'ihau (Reeves and Amidon, 2018). Over 70% of the biome occurs on the island of Hawai'i (Table 3; Fig. 5). Over half of the mesic grassland and shrubland biome in the state of Hawai'i occurs on private land. The remaining portion is owned by the federal, state and local government (Table 5, Fig. 10).

Native subtypes

Native grasslands and shrublands compose approximately 33% (148,895 ac; 60,256 ha) of all mesic grasslands and shrublands. Most of the native mesic lowland and subalpine shrublands occur on Hawai'i, Maui, Moloka'i, Lāna'i, and O'ahu. Of this, the majority occurs on Hawai'i (130,071 ac; 52,638 ha) and Maui (13,965 ac; 5651 ha). The remaining native shrubland occurs on Moloka'i (3116 ac; 1261 ha), Lāna'i (665 ac; 269 ha), and O'ahu (4 ac; 1.6 ha). The total amount of native *Deschampsia* grassland is 1074 ac (435 ha) occurring primarily on the island of Maui (Table 4, Fig. 9).

Introduced subtypes

Introduced grasslands and shrublands account for 67% (308,536 ac; 124,860 ha) of the available mesic grassland and shrubland biome statewide. A small amount of mixed native/introduced grassland and shrubland is also found on the island of Moloka'i (498 ac; 201 ha) (Table 4, Fig. 7).

Table 2 Characteristics of current mesic grasslands and shrublands in Hawai'i.

Mesic grassland and shrubland subtypes (subcategories)	Precipitation (mm)	Elevation (m)	Characteristic plants
Lowland mesic shrubland	1000–2000 mm	30–850 m	<i>Metrosideros polymorpha</i> ('ōhi'a), <i>Leptecophylla tameiameia</i> (pūkiawe), <i>Dodonaea viscosa</i> ('a'ali'i), <i>Eragrostis variabilis</i> (kāwelu), <i>Tetramolopium lepidotum</i> , <i>Dicranopteris linearis</i> , <i>Osteomeles anthyllidifolia</i> ('ūlei), <i>Lipochaeta</i> spp. (nehe), <i>Wilkesia gymnoxiphium</i> , <i>Wilkesia hobbdi</i> (iliau)
Subcategories: • 'Ōhi'a • Pūkiawe/'A'ali'i • 'Ūlei • Nehe • Iliau			
Subalpine mesic shrubland	1300–1900 mm	1950–2300 m	<i>Sadleria cyatheoides</i> (ama'u), <i>Vaccinium calycinum</i> , <i>Vaccinium reticulatum</i> ('ōhelo)
Montane-subalpine mesic grassland	1300–1900 mm	1680–2100 m	<i>Carex</i> spp., <i>Coprosma montana</i> (pilo), <i>Deschampsia nubigena</i> , <i>Dubautia</i> spp.
Subcategories: • <i>Deschampsia nubigena</i>			
Lowland mesic grassland	750–1000 mm	300–2000 m	<i>Luzula hawaiiensis</i> , <i>Leptecophylla tameiameia</i> (pūkiawe) Native: <i>Eragrostis variabilis</i> (kāwelu), <i>Bidens</i> spp. (ko'oko'olau), <i>Dodonaea viscosa</i> (a'ali'i), <i>Gouania hillebrandii</i> , <i>Metrosideros polymorpha</i> ('ōhi'a), <i>Metrosideros tremuloides</i> ('ōhi'a) Non-native: <i>Andropogon virginicus</i> (Broomsedge), <i>Melinis minutiflora</i> (Molasses grass) and <i>Schinus terebinthifolius</i> (Christmas berry), <i>Schizachyrium condensatum</i> (Beard grass)
Subcategories: • Kāwelu			
Non-native: • Molasses grass • Beardgrass			
Introduced perennial grassland	1300–1900 mm	Unrestricted	<i>Urochloa maxima</i> (guinea grass), <i>Pennisetum purpureum</i> (elephant grass) or <i>Hyparrhenia hirta</i> (thatching grass); medium-tall grasses like <i>Pennisetum setaceum</i> (fountain grass), <i>Brachiaria mutica</i> (California grass), <i>Panicum virgatum</i> (switch grass), or <i>Schizachyrium condensatum</i> (beard grass); or shorter grasses such as <i>Andropogon virginicus</i> (broomsedge), <i>Cymbopogon refractus</i> (barb wire grass), <i>Cynodon dactylon</i> (bermuda grass), <i>Melinis minutiflora</i> (molasses grass), <i>Melinis repens</i> (natal red top), <i>Paspalum conjugatum</i> (Hilo grass), <i>Pennisetum ciliare</i> (buffel grass), <i>Pennisetum clandestinum</i> (kikuyu grass)
Introduced deciduous shrubland	1300–1900 mm	Unrestricted	<i>Leucaena leucocephala</i> (haole koa), <i>Acacia confusa</i> , <i>Acacia mearnsii</i> , <i>Caesalpinia decapetala</i> , <i>Lantana camara</i> , <i>Rubus argutus</i> , and <i>Rubus discolor</i>
Introduced evergreen shrubland	1300–1900 mm	Unrestricted	<i>Schinus terebinthifolius</i> (Christmas berry) and <i>Ulex europaeus</i>

Gagne and Cuddihy, 1999; Landfire, 2016.

Non-native mesic grasslands, which include both introduced perennial and lowland mesic grasslands, account for 248,425 ac (100,534 ha) statewide and occur primarily on the islands of Hawai'i (175,670 ac; 71,091 ha), Maui (35,826 ac; 14,498 ha), Kaua'i (27,823 ac; 11,262 ha), O'ahu (7437 ac; 3010 ha), Moloka'i (1405 ac; 569 ha), and Lāna'i (264 ac; 107 ha). The non-native mesic shrubland, which includes both the introduced evergreen and deciduous shrubland sub-types, totals 60,111 ac (24,326 ha) statewide. These sub-types occur on Hawai'i (19,581 ac; 7924 ha), Kaua'i (17,593 ac; 7120 ha), O'ahu (13,599 ac; 5503 ha), Moloka'i (4004 ac; 1620 ha), Maui (3377 ac; 1367 ha), Lāna'i (1268 ac; 513 ha), and Ni'ihau (689 ac; 279 ha) (Table 4, Fig. 9).

Stressors

Hawai'i mesic grasslands and shrublands are vulnerable to impacts of stressors occurring from climate and non-climate threats since they are sensitive to biotic and abiotic factors associated with both of these (Hilberg et al., 2018). Table 6 lists the stressors for mesic grasslands and shrublands and the major stressors are described in further detail below.

Fig. 5 Current distribution of the mesic grassland and shrubland system on the island of Hawai'i.

Climate stressors

Precipitation, wind, drought, soil moisture, air temperature, and storms

One of the most sensitive climatic components of the mesic grasslands and shrublands is water availability as a function of altered precipitation levels, soil moisture, drought, air temperature, and presence of trade winds. For example, reduced water availability can directly alter vegetation composition and distribution in these communities by favoring growth and germination of invasive plants with higher tolerance for drier or wetter conditions (Hilberg et al., 2018; Camp et al., 2018).

Fig. 6 Current distribution of the mesic grassland and shrubland system on the islands of Kaua'i and Ni'ihau.

The impact of changes in climate are likely to influence the distribution of native and introduced plant species ranges across the Hawaiian islands (Price et al., 2012). Climate modeling at Hawai'i Volcanoes National Park suggest that some native montane mesic grassland and shrubland species with narrow moisture requirements may diminish as components in mesic shrublands, or possibly migrate to wetter biomes. The same analyses found that dry biomes of the park may transition to more mesic biomes with changing climate (Camp et al., 2018). An increase in precipitation and flooding may also increase the frequency of landslides which can destroy mesic grasslands and shrublands and alter their succession, particularly in areas with poor drainage or on steep slopes and valleys (Restrepo and Vitousek, 2001; Walker, 1999).

One of the primary questions regarding the possible impacts of warming temperatures on climate in Hawai'i is whether the trade wind inversion layer will be affected. If the height or frequency of the inversion layer changes due to warming, significant hydrological and ecological changes to vegetation communities can be expected (Loope and Giambelluca, 1998; Krushelnycky et al., 2016).

Non-Climate stressors

Invasive species

Invasive species, including plants and animals, are a prominent stressor for the Hawaiian mesic grassland and shrubland ecosystem since many of the native species evolved in isolation in the absence of mammalian herbivores and plant competitors (Weller et al., 2011; Dunkell et al., 2011). Some invasive plants are less susceptible to drought and less palatable to invasive herbivores and therefore may thrive when disturbance events occur and outcompete the native mesic grassland and shrubland vegetation (Weller et al., 2011). Introduced grasses also impede the germination of native seeds (Baker et al., 2009). Invasive plants capable of modifying lowland mesic shrubland communities include *Psidium* spp., *Morella faya*, *Schinus terebinthifolius*, and *Melinis minutiflora*. Feral ungulates (pigs, goats, and deer) consume and trample new growth and seedlings of native vegetation, and also promote the spread of invasive plant seeds through fecal matter causing further degradation of the mesic areas (Dunkell et al., 2011; Gagne and Cuddihy, 1999). Feral pigs and goats are the primary source of disturbance in the subalpine mesic grasslands and shrublands, and both facilitate the spread of invasive plants in disturbed areas (Gagne and Cuddihy, 1999). Examples of the effects of introduced species on mesic grasslands and shrublands follow.

Fig. 7 Current distribution of the mesic grassland and shrubland system on the islands of Moloka'i, Lāna'i, Maui and Kaho'olawe.

Fig. 8 Current distribution of the mesic grassland and shrubland system on the island of O'ahu.

Table 3 Distribution and area of mesic grassland and shrublands in the Hawaiian islands [Reeves and Amidon, 2018](#).

Island	Area in acres (hectares)	Area (% of island)	% of State of Hawai'i
Ni'ihau	689 (279)	1	< 1
Lāna'i	2198 (890)	2	< 1
Moloka'i	9022 (3651)	5	< 1
Kaua'i	45,416 (18,379)	13	1
O'ahu	21,043 (8516)	6	1
Maui	54,244 (21,952)	12	1
Hawai'i	325,322 (131,653)	13	8

Table 4 Current amount of mesic grassland and shrubland by subcategory [Reeves and Amidon, 2018](#).

Subcategory	Acres (hectares)
Mixed native-non-native mesic shrubs and grass	498 (202)
Native <i>Deschampsia</i> grassland	1074 (435)
Native mesic shrubland	147,821 (59,821)
Non-native mesic grassland	248,425 (100,534)
Non-native mesic shrubland	60,111 (24,326)
Total	457,929 (185,317)

- Lowland mesic grasslands are defined by two introduced sub-types: the Introduced molasses grass (*Melinis minutiflora*) and beardgrass (*Andropogon virginicus*) communities, both of which were primarily formed due to invasive species. These sub-types are present on most of the main Hawaiian islands and overlap with the native mesic shrublands and kāwelu grasslands. Lowland mesic grasslands, and more recently formed sub-types including introduced perennial grasslands, have been sculpted by human activity following the development of ranching, disturbance, and subsequent invasion of non-native weeds and browsing ungulates. In some lowland areas where native vegetation no longer exists and fires have been curtailed, mesic grasslands may be successional to introduced shrublands and forests, often composed of species such as Christmas berry (*Schinus terebinthifolius*) and firetree (*Myrica faya*) ([Gagne and Cuddihy, 1999](#); [MISC, 2018](#)).
- Introduced perennial grassland sub-types developed after the conversion of native lowland mesic forests and shrublands to grasslands following the arrival of humans in the Hawaiian islands ([Cuddihy and Stone, 1990](#); [Kirch, 1982](#)). The conversion from native-dominated ecotypes to entirely introduced grasslands is the result of human activity and disruptions brought by fire and introduced species, e.g., grazing ungulates. ([Gagne and Cuddihy, 1999](#)).
- Introduced evergreen and deciduous shrublands are defined by a dominant invasive vegetation community. In areas where the native vegetation no longer exists in lowland mesic grasslands, and fires have been curtailed, grasslands appear to be successional to introduced evergreen shrublands dominated by introduced species such as Christmas berry (*Schinus terebinthifolius*) ([Gagne and Cuddihy, 1999](#)). Christmas berry and gorse (*Ulex europaeus*) are both fire resilient and can prevent or inhibit the growth of other plants by releasing chemicals ([MISC, 2018](#)). Gorse is a thorny shrub that grows up to 6 ft. (2 m) tall and is only found on Maui, Molokai, and Hawaii. It forms dense thickets excluding almost all other species. This sub-type has also been shaped from browsing by invasive ungulates.

Agriculture, grazing, and urban development

Continued human population growth on all of the main Hawaiian islands has increased the need for additional housing and development ([State of Hawai'i, 2016](#)). Additional development threatens mesic grasslands and shrublands that exist primarily on private land across the islands ([Table 5, Fig. 10](#)).

Currently, most cattle grazing takes place on private and state-leased lands. However, cattle persist in many areas where inadequate or absent fencing has allowed them to wander into native-dominated areas. Unmanaged cattle are widely recognized as a major destructive agent in Hawai'i's ecosystems and have had a significant effect on montane mesic communities ([State DLNR, 2016](#)). Introduced pasture grasses brought to the Hawaiian Islands for the purpose of cattle ranching have also spread into native-dominated areas ([Cuddihy and Stone, 1990](#)).

Wildfire

The proliferation of invasive grasses adapted to fire and the increased incidence of human ignited fires have resulted in an altered fire regime that is more frequent and severe, and increasing as much as fivefold in frequency since the 1970s ([Abrahamson, 2013](#)). Fire is considered to be a primary threat to mesic grasslands and shrublands due to invasive grass fuels ([USFWS, 2010](#)). Some native plant

Fig. 9 Summary of mesic grassland and shrubland vegetation classifications.

species found in mesic grasslands and shrublands (e.g., ‘a‘ali‘i, ‘ōhi‘a, and ‘ūlei), show some tolerance of fire but most species (e.g., pūkiawe), are severely set back, killed, or compete poorly with alien vegetation when impacted by fire (Smith and Tunison, 1992).

Fire can create a cycle of spiraling degradation where cumulative effects of fire feed into the cycle of replacement with a greater percentage of invasive plants that are more susceptible to fire (leading to more frequent and severe fires and greater proportion of invasive plants). Fire affects the sub-types of the mesic grassland and shrubland differently. For example, the fire potential is considered to be relatively high in the montane mesic zone due to the continuous arrangement of grasses and abundance of shrubs (Smith and Tunison, 1992; USFWS, 2010). Fires in the lowland mesic grasslands have increased due to the presence of mat-forming and fire-adapted grasses (*Pennisetum clandestinum* and *Pennisetum setaceum*). The effect of fire on the introduced perennial grasslands has resulted in an increased fire frequency due to fire-adapted grasses and the development of secondary fire-climax grassland communities from coastal to subalpine environments (Gagne and Cuddihy, 1999). The introduced evergreen shrublands are able to recover from the effects of wildfire with fire adapted species such as gorse, whose seeds quickly germinate after fires (DLNR, 2018). Fire intensifies deciduous shrublands by increasing the cover of koa haole, which resprouts from the base and becomes established from seed (Smith and Tunison, 1992).

Natural disasters

Mesic grasslands and shrublands are susceptible to natural disasters such as volcanic eruptions and lightning fires that may remove vegetation and alter succession (Hilberg et al., 2018). These events can cause extensive damage over short time periods but are generally localized in their extent and occur only on the volcanically active island of Hawai‘i. Regeneration of native mesic grasslands and shrublands is slow on these newly created volcanic substrates, beginning with the growth of lichens and pioneer species. Substrate age, climatic moisture, and elevation are the primary drivers of rates of succession. Succession rates in mesic biomes are slower than in wet areas but faster than in dry and arid regions (Carlquist, 1980; Price et al., 2012).

Biological

The significant population decline of seabirds has likely had a negative impact on mesic biomes, including native mesic grasslands and shrublands. Seabirds contribute marine derived nutrients, especially nitrogen, to mesic areas through deposition of guano

Table 5 Land ownership of mesic grasslands and shrublands in Hawai'i (Reeves and Amidon, 2018).

Island	Land ownership	Area in acres (hectares)	Area (% of island)	Area (% of State of Hawaii)
Ni'ihau	Private	689 (279 ha)	1	<1

Table 7 Reserves of high conservation importance for the native mesic grassland and shrubland biome.

<i>Protected area</i>	<i>Location information</i>	<i>Landowner/manager</i>	<i>Total protected acreage (ac)</i>
Haleakalā National Park	Maui	Federal	33,265 ac (13,462 ha)
Hawai'i Volcanoes National Park	Hawai'i	Federal	207, 635 ac (84, 027 ha)
Kamakou Preserve	Moloka'i	Nature conservancy	1220 ac (494 ha)
Waikamoi Preserve	Maui	Nature conservancy	5230 ac (2116 ha)
Kona Hema Preserve	Hawai'i	Nature conservancy	8107 ac (3281 ha)
Kona National Wildlife Refuge	Hawai'i	Federal	3737 ac (1512 ha)
Keauhou	Hawai'i	Private	22,723 ac (9196 ha)

Conservation importance refers to the protected areas relative priority and how it falls within resilience, representation, and redundancy.

Table 8 Laws and regulations.

<i>Title</i>	<i>Year implemented</i>	<i>Authority</i>	<i>Intent/purpose</i>
Endangered Species Act	1973	Federal	Protects critically imperiled species from extinction
50 CFR 16	1974	Federal	Implements the Lacey Act (18 USC 42), which prohibits importation of injurious species
Convention on International Trade in Endangered Species	1975	International	Ensures that international trade in specimens of wild animals and plants does not threaten the survival of the species in the wild
Executive Order 11987	1977	Federal	Charges Executive agencies with restricting the introduction of exotic species into the natural ecosystems on federal lands; and encourages States to do the same
Hawai'i Administrative Rules, Title 4, Subtitle 6, Chapters 68 and 70	1981	Hawai'i (Department of Agriculture, DOA)	Rules/amendments for noxious weeds, plant and non-domestic animal quarantine, plant import, and bromeliad import
Executive Order 13112	1999	Federal	Requires that a Council of Departments dealing with invasive species be created to prevent the introduction of invasive species and provide for their control and to minimize the economic, ecological, and human health impacts that invasive species cause
HRS 194-2	2002	Hawai'i (Department of Land and Natural Resources, DLNR)	Establishes Hawaii Invasive Species Council (HISC)
Act 85	2003	Hawai'i (HISC)	Conveys statutory authority to HISC to continue to coordinate approaches among the various State and Federal initiatives for the prevention and control of invasive species
Act 36 (2011) HRS 150A-5.3	2011	Hawai'i (DOA)	Imposes a fee for the inspection, quarantine, and eradication of invasive species contained in any freight brought into the State
HB 1568	2011	Hawai'i (DOA)	Requires commercial harbors and airports in Hawai'i to provide biosecurity and to facilitate cargo inspections

Table 9 Responses of mesic grassland and shrubland stressors in foreseeable future scenarios (Amidon and Reeves, 2018).

Conservation management parameters (CMPs)				
Conservation values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans			
Laws and biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented			
Planning for development or conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation)			
Foreseeable Future Scenarios and the resulting mesic grassland and shrubland conditions				
Use Foreseeable Future Scenario one as a “baseline” to characterize changes in <i>Conservation actions</i> and <i>Ecotype conditions</i> in Future Scenarios Two, Three, and Four	Scenario One <i>CMPs</i> : Unchanged in support for NRC/B <i>Conservation actions</i> : No change; current rate of land cover change continues through the foreseeable future <i>Ecotype condition</i> : habitat area, quality, and sustainability slowly decrease through the foreseeable future	Scenario Two <i>CMPs</i> : Small increase in support for NRC/B <i>Conservation actions</i> : Marginal increase <i>Ecotype condition</i> : Habitat area is unchanged through the foreseeable future; habitat quality and sustainability are slightly enhanced through the foreseeable future	Scenario Three <i>CMPs</i> : Small to moderate decrease in support for NRC/B <i>Conservation actions</i> : Substantial decrease <i>Ecotype condition</i> : Urban and agricultural uses are prioritized over conservation; habitat area, quality, and sustainability substantially decrease through the foreseeable future	Scenario Four <i>CMPs</i> : Moderate to high increase in support for NRC/B <i>Conservation actions</i> : Substantial increase <i>Ecotype condition</i> : Robust, sustained effort to restore, manage, and expand conservation; habitat area, quality, and sustainability substantially increase through the foreseeable future
Stressors	Responses of mesic grassland and shrubland stressors			
Development	Small to moderate increase	No change (redevelop)	Moderate to high increase	Small to moderate decrease

Introduced perennial grassland	Increase	Increase	Increase
Introduced deciduous shrubland	Increase	Increase	Increase
Introduced evergreen shrubland	Increase	Increase	Increase

(Rowe et al., 2017). In addition, the loss of native insect pollinators has reduced the pollination of some native Hawaiian plant species resulting in lower rates of regeneration (Aslan et al., 2013; Price and Wagner, 2004). The overall decline of native birds, including seed dispersing native passerines and the Hawaiian goose (*Branta sandvicensis*) also limits the regeneration of native shrublands where these species once occurred (Culliney et al., 2012).

Conservation Efforts

Reserves

Approximately 82,477 (33,377 ha) of mesic grasslands and shrublands are protected in reserve areas across the main Hawaiian Islands (Fig. 11). Reserve areas are defined as those designated as parks and reserves. These may include areas designated as a national park, national wildlife refuge, Natural Area Reserve (NAR), or Nature Conservancy preserves (Reeves and Amidon, 2018). The amount of mesic grasslands and shrublands protected in reserve areas varies by island, with 66,012 ac (26,714 ha) on the island of Hawai'i, 11,040 ac (4468 ha) on Maui, 2702 ac (1093 ha) on Moloka'i, 2402 ac (972 ha) on Kaua'i, and 321 ac (130 ha) on O'ahu (Fig. 11). Of the 66,012 ac (26,714 ha) protected in reserves areas on the island of Hawai'i roughly 45,288 ac (18,327 ha) are classified as native dominated habitat (Fig. 11). Lāna'i and Ni'ihau contain the least amount of mesic grasslands and shrublands protected in reserve areas in the State with <3 ac (1 ha) on both Lāna'i and Ni'ihau (Fig. 11). Knowing that <82,477 ac (33,377 ha) of mesic grasslands and shrublands are protected in reserve areas in the State, and 457,929 ac (185,317 ha) are actually classified as mesic grasslands and shrublands in the State, indicates a need to implement additional measures to increase the public's awareness of the remaining gap between unprotected versus protected mesic grasslands and shrublands.

Active conservation efforts that benefit native mesic grassland and shrubland communities are underway in protected reserves and within watershed management areas. These efforts include wildfire threat control, invasive species management, exclusion fencing for ungulates, and removal of non-native ungulates and weeds. The islands of Hawai'i, Maui, and Moloka'i have the most intact areas of remaining native-dominated mesic grasslands and shrublands in the state (Fig. 12). Reserves of high conservation importance for the native mesic grassland and shrubland biome are included in Table 7.

Fig. 11 Quality of mesic grasslands and shrublands in reserves.

Fig. 12 Quality of the mesic grassland and shrubland system.

Laws and biosecurity

Endangered species protections and state and federal biosecurity laws, regulations, coordination, and authority aid in conservation efforts for native mesic grasslands and shrublands by preventing the introduction of invasive species and providing legal protections for rare native species (Table 8).

Biosecurity

In addition to federal biosecurity laws (Executive Orders 11,987, 13,112, 13,751), the Hawai'i Invasive Species Council (HISC) adopted Resolution 17-1 endorsing the Hawai'i Interagency Biosecurity Plan. This Interagency Biosecurity Plan is the state's guiding document for biosecurity improvements over the coming decade. Invasive species are a primary stressor for mesic grasslands and shrublands and therefore prevention and management across the state of Hawai'i is essential to protect the remaining mesic grasslands and shrublands.

Endangered species act

The Endangered Species Act (ESA) of 1973 and its amendments provides a framework to conserve and protect endangered and threatened species and their habitats.

The ESA prohibits "Take" (broadly defined to include "harass, harm, pursue, hunt, shoot, wound, kill, trap, capture or collect") endangered animal. Furthermore, the U.S. Fish and Wildlife Service (USFWS) has declared that "harm" includes "significant habitat modification or degradation." Thus, the habitat as well as the endangered animal is protected.

Critical habitat:

The ESA establishes "critical habitat" is a regulatory link between habitat protection and recovery goals for species. "Critical habitat" is defined as "all lands, water and air necessary to recover endangered species." To determine what exactly is critical habitat, the needs of open space for individual's and population's growth, food, water, light or other nutritional requirements, breeding sites, seed germination and dispersal needs, and lack of disturbances are considered (USFWS, 1998).

As habitat loss is the primary threat to most imperiled species, the ESA as enacted in 1973 allowed the USFWS and National Marine Fisheries Service (NMFS) to designate specific areas as protected "critical habitat." In 1978, Congress amended the law to make critical habitat designation a mandatory requirement for all threatened and endangered species. Fourteen percent (63,898 ac; 25,859 ha) of mesic grassland and shrubland habitat in the state of Hawai'i is designated as Critical Habitat (Fig. 13). Mesic grassland and shrubland in Hawai'i provide habitat for many endangered plant, insect, and forest bird species, and as a result receive protection through the ESA, and in particular, the protection of critical habitat for these listed species.

Fig. 13 Federally designated critical habitat on the main Hawaiian islands containing mesic grasslands and shrublands.

Stakeholder engagement

National parks

A total of 71,396 ac (28,893 ha) of mesic grasslands and shrublands exist on federal lands in the Hawaiian islands (Table 7). Of this, approximately 90% occurs on the islands of Hawai'i and Maui, primarily within Hawai'i Volcanoes and Haleakalā National parks (Tables 5 and 7). Management actions that benefit native mesic grasslands and shrublands within the national parks include fencing, ungulate removal, and invasive weed control (NPS 2015, 2016).

State of Hawai'i

A total of 171,380 ac (69,355 ha) of native and non-native mesic grasslands and shrublands exist on state lands, primarily within State Forest Reserves (FRS), state parks, and in Natural Area Reserves (NARS) (Table 5). The largest proportion of this biome occurring on state lands is found on the islands of Maui and Hawai'i (Fig. 10).

The Forest Reserve System (FRS) was created by the Territorial Government of Hawai'i in 1903 as early foresters recognized the need to protect forests to provide water for agriculture and surrounding communities. The FRS encompasses over 678,612 ac (274,624 ha) of land statewide, some of which includes lowland and subalpine mesic grasslands and shrublands. The Department of Land and Natural Resources, Division of Forestry and Wildlife (DOFAW) focus their resources to protect, manage, restore, and monitor the natural resources of the FRS (DOFAW, 2018).

The Natural Area Reserves System (NARS) was established in 1970 with the intent to preserve in perpetuity specific land and water areas which support communities, as relatively unmodified as possible, of the natural flora and fauna, as well as geological sites, of Hawai'i. The Natural Area Reserves are administered by the Division of Forestry and Wildlife (DOFAW) within the Department of Land and Natural Resources (DLNR). The Mt. Ka'ala and Pahole Natural Area reserves on O'ahu contain native lowland mesic shrublands. Some management actions taking place within the NARS include construction of feral ungulate exclosure fences, ungulate management, weed control, and outplanting of native species.

Department of Hawaiian Home Lands

The Department of Hawaiian Home Lands (DHHL) was created by the Hawai'i State Legislature in 1960 and is governed by the Hawaiian Homes Commission Act of 1920. The act set aside a land trust for native Hawaiians to maintain their traditional ties to the land. The primary responsibility of DHHL is to serve its beneficiaries and manage its land trust. DHHL also views its responsibility as a landowner to manage and protect native lands "to support both cultural and resource management activities and create homesteading opportunities for the future" (DHHL, 2009). Thus, the 'Āina Mauna Legacy Program was created to protect native forest (including shrublands) on the slopes of Mauna Kea on the island of Hawai'i. The program specifically includes the lands of Humu'ula and Pi'ihonua, which contain native mesic shrublands and introduced evergreen shrublands. Management goals include removal of invasive species (*Ulex europaeus*), native ecosystem protection and restoration, conserving endangered species, and providing educational and cultural opportunities (DHHL, 2009).

Watershed partnerships

The Hawai'i Association of Watershed Partnerships (HAWP) is composed of 10 island-based watershed partnerships that work collaboratively with >74 public and private partners on five islands to protect over 2.2 million ac (890,308 ha) of vital forested watershed lands (HAWP, 2018).

The HAWP's mission is to increase the effective management and protection of upper elevation watershed areas by raising the capacity of watershed partnerships, facilitating the sharing of watershed management expertise, building public support for protecting watershed values, and developing sustainable funding sources. Watershed partnerships undertaking conservation actions that protect and manage significant areas of native mesic grasslands and shrublands include the Three Mountain Alliance Watershed Partnership, Mauna Kea Watershed Alliance, Leeward Haleakalā Watershed Restoration Partnership, East Maui Watershed Partnership, West Maui Mountains Watershed Partnership, and the East Moloka'i Watershed Partnership.

Safe Harbor agreements

The Federal and State Safe Harbor programs encourage proactive conservation efforts by non-Federal landowners while providing them certainty that future property-use restrictions will not be imposed if those efforts attract species listed as endangered or threatened to their property, or result in increased populations of endangered or threatened species already present. In return for voluntary conservation commitments, the Agreement gives the landowner assurances covered by agency permits that allow for future alteration or modification of the enrolled property back to its original condition. These cooperative efforts provide landowners with a way to manage their lands to support the conservation of listed species while conducting approved land-use practices. Without this cooperative government/private effort, the private property would be less valuable to the recovery of endangered or threatened species (State BLNR, 2018).

A Safe Harbor Agreement between Kamehameha Schools, the State Department of Land and Natural Resources, and the USFWS was finalized in June of 2018. The total area covered by the agreement is 32,207 acres (13,034 ha) on lands owned by Kamehameha Schools on the island of Hawai'i. The area covered by the SHA includes mesic grasslands and shrublands. The 50-year agreement will contribute to the recovery of 32 endangered species and the agreement is part of an ongoing watershed partnership effort within the State of Hawai'i managed by the Three Mountain Alliance Watershed Partnership. Management activities benefiting mesic

shrublands and grasslands include control of invasive plants, fencing and ungulate removal, and fire threat management (TMA, 2007; State BLNR, 2018; KS, 2014).

Pūlama Lāna'i

The island of Lāna'i is privately owned but is developing an island-wide management plan in coordination with the USFWS and other partners. The land manager, Pūlama Lāna'i, is implementing actions that benefit mesic shrublands inside the Lāna'ihale unit (Increments 1 and 2). The management unit protects a total of 2200 ac (5436 ha) and ongoing management actions include the control of invasive ungulates and weeds (Lāna'i Resorts et al., 2015, in. litt.).

Ranching and farming easements

Land eligible for agricultural easements that overlaps with the mesic shrub and grassland communities are generally composed of rangeland, grassland, pastureland and nonindustrial private forest land. The Natural Resources Conservation Service (NRCS) prioritizes the protection of agricultural uses and related conservation values of the land and those that maximize the protection of contiguous acres devoted to agricultural use. Private landowners and lessees may enroll land through agricultural land easements through NRCS. Easements are contingent on the development of an agricultural land easement plan that promotes the long-term viability of the land (USDA, 2018).

Invasive species committees (ISC)

Invasive species are a prominent stressor for Hawai'i's native ecosystems, including mesic grasslands and shrublands. The State has developed a group of invasive species committees (ISC's) to focus on priority threats identified by each island. The ISC's are voluntary island-based partnerships on Kaua'i (KISC), O'ahu (OISC), Maui (MISC), Moloka'i (MOMISC), and the Big Island (BIISC) that work with government agencies, non-profit organizations, and private businesses and landowners to protect each island from the most threatening invasive species with a proactive approach. The ISC's target species that have high potential to severely impact the economy, environment, agriculture, human health, and quality of life (HDLNR, 2015).

The ISC's are invaluable to the protection and restoration of mesic grasslands and shrublands because of the significant impacts invasive plants and animals have on these communities. The ISCs work contributes directly to the conservation of mesic grasslands and shrublands through removal and reduction of invasive plants and animals in mesic grassland and shrubland areas and in restoration of these sites across the Hawaiian islands.

Hawai'i Wildfire Management Organization (HWMO)

The introduction and spread of invasive fire-adapted grasses and increased human-caused ignitions are important contributors to the increased incidence of fire, particularly in lowland mesic shrublands and perennial grasslands. Since 2002, the Hawai'i Wildfire Management Organization (HWMO) has worked with communities throughout the State of Hawai'i to implement dozens of projects mitigating wildfire hazards and protecting natural and cultural resources. They have also partnered extensively with a variety of organizations from the U.S. Forest Service, U.S. Army and University of Hawai'i, to the grassroots small community associations of Hawai'i's towns and villages (HWMO, 2018, in litt.). Their work includes sponsoring community wildfire preparedness workshops and conducting wildfire hazard assessments for every community in the state. These assessments provide a more thorough understanding of wildfire hazards that can be addressed by communities, decision makers, fire responders, and natural resource managers. This organization directly supports the conservation of mesic grasslands and shrublands through preparation and education efforts to minimize destruction of mesic grasslands and shrublands by wildfires (HWMO, 2018, in litt.).

Future Scenarios

We analyzed the future condition and viability of the mesic grasslands and shrublands in Hawai'i based on four possible future scenarios using a series of analyses based on land cover maps and projected changes over time (Miller, 2018). The condition of Hawai'i's mesic grasslands and shrublands in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

- (1) *Conservation values*: Stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
- (2) *Laws and biosecurity*: National, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented. (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
- (3) *Development or conservation planning*: National, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the "foreseeable future," and is based on the

projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuuren, et al., 2011a,b; Miller, 2018) for a definition and description of the determination of the foreseeable future.

The four foreseeable future scenarios considered in this habitat assessment are:

Future Scenario One, Status Quo—The most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future.

Future Scenario Two—A slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future Scenario Three—A slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Future Scenario Four—A moderate to large increase in conservation actions in the CMPs substantially improves conservation management.

The future condition of mesic grasslands and shrublands in Scenario One, the status quo, was characterized from an assessment of change over time in mesic grassland and shrubland land cover obtained from existing land cover maps by Amidon and Reeves (2018). Based on these land cover maps, an annual rate of change for mesic grasslands and shrublands was estimated, and a projected change (in acres/hectares) was calculated for the year 2035. The resulting information on changes in land cover by 2035, as derived from existing land cover change estimates, is the extent of the mesic grasslands and shrublands that is expected in the foreseeable future under Scenario One, the status quo, where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged (Amidon and Reeves, 2018).

The future conditions of mesic grasslands and shrublands for Scenarios Two, Three, and Four cannot be quantitatively (acres/hectares) estimated. However, the Scenario One estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of mesic grasslands and shrublands under Scenarios Two, Three, and Four.

Changes in human population are captured only by the changes in the “developed” land cover footprint derived from land cover map analysis (Amidon and Reeves, 2018). Impacts from other sources of human activities or human-caused habitat stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by non-native vegetation. For an assessment of island-by-island changes in human population, see Amidon and Reeves (2018).

Also, note that island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions which occurs on the order of centuries rather than years (Solomon et al., 2009; Gillett et al., 2011; Jevrejeva et al., 2012). Evidence of climate effects is also confounded by the large annual variation in the Pacific islands climate parameters, which is much greater than projected climate change by 2035. Although impacts from climate-related habitat stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future habitat viability.

Future scenario one—status quo

Summary: Scenario One is considered the most likely future scenario, and serves as a “baseline” for comparing among the four future scenarios. There is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in mesic forest sub-categories (Table 9).

Under Scenario One, native mesic grasslands and shrublands would have a continued decline in size and distribution, and therefore a decrease in redundancy. Human caused stressors will have a small increase overall and continue to reduce the size and quality of native mesic grasslands and shrublands. Ecological function is predicted to be reduced due to the ability of invasive plants and animals to outcompete native plants for water and space, subsequently resulting in a reduction in native biodiversity. Degradation of native mesic grasslands and shrublands will continue to increase as remaining areas become more fragmented, thus reducing their resiliency and representation.

Introduced mesic grasslands and shrublands are predicted to increase in size and distribution (redundancy) as a result of the overall small increase in human-caused ecotype stressors. Introduced perennial grasslands and introduced shrublands are likely to expand as invasive species replace native-dominated communities, resulting in an increase in resiliency, redundancy, and representation (Table 10).

Future scenario two

There is a slight increase in the CMPs that marginally improves conservation management.

Under Scenario Two, conservation agencies and stakeholders work with increased but limited resources to slow or stop the degradation of native mesic grassland and shrubland areas. Introduced perennial grasslands and introduced shrublands will continue to increase. Scenario Two is essentially “status quo” with minor improvements in the three CMPs. This scenario is expected to have the second highest likelihood of occurring into the foreseeable future, being slightly less likely than Scenario One (Table 10).

Future scenario three

There is a small to moderate decrease in conservation actions in the CMPs that substantially decreases conservation management,

All natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in park-like settings or in areas where land development is not possible. This scenario has substantial declines in natural resource conservation within the three CMPs. An increasing human population is supported in its use of land for economic development over the conservation of native ecotypes. Areas that cannot support development become the only areas of free-living native species. The anticipated changes, under Scenario 3, for each of the ecotype stressors important to mesic grasslands and shrublands are given in [Table 9](#).

Overall, this scenario would severely degrade and fragment native mesic grasslands and shrublands and result in reduced resiliency, redundancy, and representation. Introduced mesic grassland and shrubland sub-types would significantly increase in resiliency, redundancy, and representation under this scenario. This scenario, along with Scenario Four, has the lowest likelihood of occurring in the foreseeable future ([Table 10](#)).

Future scenario four

There is a moderate to large increase in conservation actions in the CMPs that substantially improves conservation management.

For this scenario, substantial improvements to the three CMPs and a general decrease in human-caused ecotype stressors would increase the size and quality (resiliency) of native mesic grasslands and shrublands. Although this increase in native grassland and shrubland sub-types would be gradual at first it will become more noticeable by 2035 as the substantial improvements to the three CMPs will help keep these sub-types from declining. The introduced mesic grassland and shrubland sub-types would slowly decrease in resiliency, redundancy, and representation under this scenario ([Table 10](#)).

Based on this analysis, the substantial improvements in restoration for native mesic grasslands and shrublands would result in their increased resiliency, redundancy, and representation while the introduced grassland and shrubland sub-types would slowly decrease. This scenario, and Scenario Three have the lowest likelihood of occurring in the foreseeable future.

Conservation Implications

Under Scenario One (Status Quo), the most likely future scenario, the native mesic grasslands and shrublands are expected to decrease in resiliency, redundancy and representation while the introduced subtypes are predicted to increase ([Tables 10 and 11](#)). Conservation efforts by Federal, State, private, and multiple agency partnerships have been beneficial in helping to conserve and protect native mesic grasslands and shrublands. Increased funding and landowner incentives must be considered a high priority by agencies and partnerships in order to expand and manage remaining native mesic grassland and shrubland communities. Without increased effort the current level of conservation measures are insufficient to conserve the native subtypes of this biome. The continued spread of invasive plant species, particularly fire-adapted introduced grasses, and the proliferation of invasive ungulates is rapidly degrading native-dominated mesic grasslands and shrublands, reducing their representation and resiliency ([Table 11](#)). The decline in marine derived nutrients from seabirds, loss of insect pollinators, and loss of native birds for seed dispersal has resulted in less resilience in the native subtypes. All of these impacts combined with changes in fire regime, climate, and water availability are more favorable to increasing resiliency, redundancy, and representation in the introduced mesic grasslands and shrublands while the native-dominated subtypes will continue to decrease ([Table 11](#)).

Abstract

This article provides an overview of the savannas of the Mariana island archipelago (Marianas) savanna biome, including current status, stressors, and future viability. Across the Marianas, savannas are typically found in mountainous areas formed by volcanic action. Tropical savanna are associated with the tropical wet and dry climate and develop in a seasonal forest of climax regions. However, edaphic conditions or disturbances prevent the establishment of species of trees associated with the climatic community (Woodward, 2012). Savanna in the Marianas generally receive between 50.8 and 127 cm (20–50 in.) of rainfall annually and are characterized by a predominance of grass and other herbaceous species with some small trees and shrubs (Webber et al., 2007). Currently, savanna ecotypes in the Marianas are experiencing severe erosion, forming badlands, which are challenging to control and restore back to native systems. Our assessment of savanna viability, defined as the likelihood of persistence over the long term, is based on the concepts of representation, redundancy, and resiliency. The main stressors to savanna in the Marianas are development, invasive species, erosion caused by recreational off-road vehicle use, fires, typhoons and drought. Current ongoing conservation efforts by Federal, State, and private entities and agency partnerships combined with certain laws and regulations limit some of the effects of stressors on the ecotype, but do not eliminate them. A stronger effort to engage partners and stakeholders in identifying and prioritizing landscape areas required for the conservation of native ecosystems, and to actively restore and expand these areas is needed for the successful conservation of savannas.

Introduction

The Mariana archipelago consists of 15 main islands and various small islets spanning a north-south distance of 553 miles (mi) (890 kilometers (km)) in the western Pacific Ocean between latitudes 21° and 13°N and longitudes 144° and 146°E. The Mariana

archipelago consists of the island of Guam and the Commonwealth of the Mariana Islands (CNMI), which consists of 14 islands located just north of Guam. The vast majority of the archipelago's land area is concentrated in the larger, southern main islands, including Saipan, Tinian, Rota, and Guam. Further information about the Mariana archipelago is described in Physical Geography of the Mariana Archipelago included in this work. This article provides an overview of the savanna in the Mariana island archipelago and describes the ecological factors that have influenced the habitat over time and into the future.

Description

The savanna community is characterized by grass and dispersed trees. Savanna are structurally simpler than forests, in that they do not provide the complexity of ecotypes above ground that forests do (Lobban and Lobban, 1997).

Climate is the most crucial factor in creating savanna. Therefore, savannas are typically found in warm or hot environments where the annual rainfall ranges from about 50.8 to 127 cm (20–50 in.) per year (Webber et al., 2007). Tropical savanna or grassland are also associated with the tropical wet and dry climate in regions where the climax community should be some form of seasonal forest or woodland, but edaphic conditions (e.g., availability of nutrients) or disturbances prevent the establishment of those species of trees associated with the climax community. Edaphic savannas are caused by soil conditions not entirely maintained by fire (Woodward, 2012).

A type of savanna that results from clearing of forest by farmers, hunters, or arsonists, either through manual clearing or setting fires, is known as derived savanna. As the grass takes over the bare ground (succession), wildfires can occur within a year of the initial human caused disturbance (Webber et al., 2007). Although seasonal fires play an important role in savanna's biodiversity, fire is not part of the Mariana's natural environment. In fact, the native plants and animals are poorly adapted to frequent burning while non-native plants thrive, altering biodiversity, an important component of ecosystem functioning (Loreau et al., 2002).

In the Northern Marianas, savanna/grasslands are typically found in mountainous areas formed by volcanic action but can also occur in limestone soils such as the Sabana Region of Rota and Mt. Tapotchau on Saipan (Falanruw et al., 1989; Liske-Clark, 2015). Savanna/grasslands also occur in the Talakhaya region of southern Rota. On Guam, savanna/grasslands are most common in the southern portion of the island where volcanic hills rise to about 1200 ft altitude. They can occur on hills or ridges where the soil is shallow, or in valleys where clay soils become waterlogged in wet weather (Stone, 1970).

"Inclusions," or sub-types, in the savanna include wetlands in depressions in the volcanic substrate that hold water; riverine systems within the savanna where natural drainage patterns hold enough moisture for native forest to grow; outplanted areas of *Acacia* forest from restoration activities, and badlands where severe erosion has stripped the soil to bare rock.

Geology

Savanna soils are red acidic clay and deeply weathered. They are usually volcanic but in a few small patches are composed of limestone (Fosberg, 1960). Volcanic soils often have a high aluminum content (Young, 1988) which restricts plant growth in acidic soils (Watanabe and Osaki, 2002). Due to the impermeable nature of the bedrock substrate under the soils, rainwater washes down the slopes and forms streams in river valleys, sometimes causing severe erosion and forming "badlands" (Young, 1988).

Badlands are highly degraded patches formed when soils and organic matter are washed off of steeply sloping terrain, exposing bare bedrock (Scheman et al., 2002; Golabi et al., 2005). Badlands usually form on heavily eroded Akina and Atate soils on Guam, Rota, and Saipan (Young, 1988, 1989). The soil of the Akina and Atate soil classification series are highly prone to erosion. Akina and Atate soils, which make up approximately 2266 acres of Guam, are found on volcanic uplands in very deep, well drained, and moderately slowly permeable terrain with slopes up to 45° (Young, 1988). Akina soils on Rota and Saipan make up approximately 203 and 1000 acres of those islands respectively, and are found on slopes ranging from 10% to 60% (Young, 1989).

Young (1988) described badlands on Guam as actively eroding areas of very deep, well-drained saprolite derived from tuff and tuff breccia. Saprolites (common in humid and tropical climates) are weathered rocks, in this case volcanic in origin, whose original textures and structures are preserved despite replacement of the fresh minerals by clay (Carroll et al., 1963). Saprolite is also strongly acidic and nutrient poor, creating a hostile environment for most plants.

Approximately 90% of Saipan's surface area is covered by limestone and calcareous sediments.

On Saipan, savanna vegetation types are supported by some relatively gray-white rocks from volcanic dacite (Raulerson and Rinehart, 1991). Dacite are 62–69% silica with moderate amounts of sodium and potassium (USGS, 2015).

Badlands are caused from sheet and rill erosion from wind and rain. Sheet erosion is caused when rain removes soil particles, leaving barren areas on the top layer of the soil. Rill erosion occurs when surface flow creates paths, sometimes leading to eroding channels. Badland soils have moderately low permeability and are vulnerable to impacts from both wind and rain, making them susceptible to severe sheet and rill erosion patterns. (Scheman et al., 2002).

Vegetation Structure

Rainfall, fire, and herbivory drive the structure and distribution of the savanna/grassland eco-type (Lehmann and Parr, 2016) (Fig. 1). The savanna/grassland of the Marianas is primarily composed of tall and short grasses, but many other shrubs, ferns,

Fig. 1 Acres of grassland and mixed grass/herbaceous vegetation in the Marianas. From Reeves, M.K. (2019). Savanna and grassland vegetation summary.

and ground orchids can be found within the landscape (Fig. 2). Tall grasses can form dense thickets while areas dominated by short grasses have ferns and ground orchids scattered throughout. Many of the plants found in the volcanic geology-based savannas tolerate conditions that are inhospitable to most plants due to the high aluminum content and low pH in the soils (Raulerson and Rinehart, 1992). Some ferns, such as *Dicranopteris linearis*, and grasses, such as the invasive species *Miscanthus floridulus* and *Pennisetum polystachion*, are highly adapted to these soils and thrive in this environment (Minton, 2006). There are few trees in savannas and they tend to be short-statured due to destruction from fires or edaphic conditions. A summary of the vegetation in the Marianas is shown in Fig. 1 below.

Fosberg (1960) and Ohba (1994) described the following types of savanna/grassland communities for the Mariana Islands: *Miscanthus floridulus*, *Dimeria chloridiformis*, *Chrysopogon aciculatus*, and erosion scar. The *Miscanthus floridulus* type is dominated by *Miscanthus floridulus* but it can also include other grasses, sedges, ferns, shrubs, and herbs (Fosberg, 1960; Falanruw, 1989; Falanruw et al., 1989; Ohba, 1994). This community type forms a tall grassland and is found, at varying extents, on all the Mariana Islands

Fig. 2 Savanna in southern Guam, showing a small clump of Casuarina trees, low shrubs and ground orchids in the right foreground. From (USFWS) U.S. Fish and Wildlife Service. (2018). Savanna in southern Guam, showing a small clump of Casuarina trees, low shrubs and ground orchids in the right foreground. (USFWS unpubl. photo).

except *Uracus* (Fosberg, 1960; Ohba, 1994). However, the most extensive coverage of this community type occurs on Guam, Rota, Saipan, Anatahan, Alamagan, Pagan, and Agrihan. The *Dimmeria chloridiformis* community, which is dominated by *Dimmeria chloridiformis*, forms a low grassland on level and gentle sloping areas and appears restricted to Guam (Fosberg, 1960). The *Chrysopogon aciculatus* community forms a low grassland on ridges and appears restricted to the islands of Anatahan, Sarigan, and Guguan (Ohba, 1994). This community is dominated by *Chrysopogon aciculatus* but also includes other sedges, ferns, and shrubs. The erosion scar community is composed of a mixture of pioneer species that establish themselves in the heavily eroded areas of the savanna (i.e., the badlands; Fosberg, 1960). This community occurs on Guam, Rota, and Saipan and includes grasses, ferns, and shrubs (Fosberg, 1960). Table 1 summarizes the plant species recorded in savannas, by savanna type, if available.

Volcanic soils composed of decomposed volcanic ash have created the Akina soils on the slopes and ridgetops in Guam, Rota and Saipan creating red, silty, clay soils. When soil is loosened by actions of fires or vehicles or left unprotected by plant cover, soil particles are exposed to the forces of wind, gravity, and surface flow of water (Golabi et al., 2005). Soils are removed from the savanna leaving bare patches of red soil, referred to as badlands. Fig. 3 shows severe erosion in the savanna. The edges of badlands tend to be ringed by ferns tolerant of intense sunlight and high soil aluminum content (Raulerson and Rinehart, 1992).

Water Availability

On volcanic soils, vegetation in savanna depends on rainfall, which does not soak directly through the soil into a water table as it does in limestone-derived soils. Bedrock lined with very deep decomposed volcanic soils form a barrier to water entry. Rain soaks into the upper layers of soil where it is held by humus and available to plants. In areas where badlands have formed, rainwater washes soil directly away, leaving dry bare rock that plants cannot hold onto (Scheman et al., 2002). Fig. 4 shows an example of a typical savanna landscape in Guam.

Pre-Human Condition

Very few detailed studies on vegetation in the Marianas have been published. Brief descriptions of the lands and vegetation by early explorers and scientists exist for some of the islands, but not all (USGS report by Tracey et al. 1964; Gressitt in 1954). The vegetation of Guam has been the most researched, with botanical publications by Fosberg (1960), Stone (1970), and Safford (1905). Two publications from Raulerson and Rinehart (1991, 1992) as well as one by Mueller-Dombois and Fosberg (1998) covering vegetation for islands throughout the Pacific are the most extensive.

While not much is known about the prehistoric condition of the savannas in the majority of the Marianas, a study by Athens and Ward (2004) analyzed soil cores to study pollen and carbon deposits as signals of ancient human activities within the landscape such as gardening, burning, and other modification on Guam. The oldest soil cores include pollen from common forest tree genera such as *Aglaia*, *Pandanus*, and *Cycas*, while pollen of common grassland and savanna plants were absent. Charcoal from human burning activities and pollen from savanna plants such as *Lycopodium cernuum* and *Gleichenia linearis* began to appear in substantial amounts approximately 2500 years ago. Before humans arrived there was no evidence of a savanna landscape on Guam (Athens and Ward, 2004). It is unknown whether or not savannas on other islands in the Marianas were also anthropogenically influenced or naturally occurring.

Current Condition

Humans first came to the Mariana Islands approximately 4000 years ago, and at that time the savanna lands were significantly smaller than today, possibly existing as small fragments within a large forest ecotype. Human activities in the uplands of southern Guam, most probably burning to clear land for farming, combined with erosion and impoverished upland soils, created savannas where forests failed to regenerate (Athens and Ward, 2004).

Fosberg (1960) describes several plant communities in the Mariana Islands, four of which are included in the savanna: (1) *Miscanthus* community, (2) *Dimeria* community, (3) erosion scar community (badlands), (4) the *Phragmites* or reed community. The *Phragmites* community however, occurs in low spots with wetland characteristics, and therefore is not covered in detail in this article. While Fosberg describes the main constituents of each of his defined communities, he neglects to specify what smaller plants can be found within each. All of these communities can exist together in very close proximity in an area termed the “savanna complex” (Mueller-Dombois and Fosberg, 1998).

The *Miscanthus* savanna community of the Mariana Islands can form monotypic dense stands 2–3 m (6.5–9.8 ft) tall, while *Dimeria* forms shorter clumps (Fosberg, 1960). The thickness of *Miscanthus* stands generally crowds out other plant life, although some climbing ferns such as *Ctenitis subglandulosa* can be found. In *Dimeria* communities with mid to tall grasses, trees such as *Casuarina equisetifolia*, *Scaevola taccada*, and *Pandanus* spp. are scattered through the landscape. Other grasses may be found here such as introduced *Pennisetum* spp. or *Paspalum* spp. Small herbs and ferns can be found in the lower layers and wet depressions in the landscape may host phragmites marshes (Mafnas, 2010). Fig. 2 depicts a typical savanna community.

During World War II, large stands of *Casuarina* trees grew on the savannas of Guam because of movement and hunting restrictions placed upon activities of the local people. Fires were reduced and *Casuarina* was able to expand. After the war, fires resumed

and the savanna *Casuarina* forests were completely destroyed on Guam and in most of Saipan by 1946 ([Mueller-Dombois and Fosberg, 1998](#)).

Although there was very little historic information about savannas in the Mariana Islands, the available literature describes a decline in the quality of several vegetation types in the Marianas once humans arrived. Pressures caused by humans have increased as populations and technologies have advanced. Early settlers burned forests to create open fields for farming. The Spanish introduced deer, which were then hunted by setting fires to burn down vegetation. In modern times, hunters continue to hunt by setting fires ([Liske-Clark, 2015](#)). New human activities of off-roading and “mudding” exacerbate erosion. Intentionally set fires and damaging activities such as off-road vehicle use lead to severe erosion, causing the development of badlands. Carabao, goats, pigs, and deer have been found to be present in some of the highest densities in the world ([Knutson and Vogt, 2002](#)), and cause erosion through wallowing, rooting, or vegetation consumption.

Savanna on Guam was formed by anthropogenic influence ([Athens and Ward, 2004](#)), and it is unknown if savanna lands on other Mariana Islands were formed in a similar fashion. [Fig. 5](#) displays current occurrences of savanna ecotype on each island in the Mariana Islands.

Maps of savanna habitat occurrences in the Marianas.

Fig. 5 (continued).

Nearly all savannas in the Mariana Islands occur on volcanic soils. However in the CNMI, a few small areas of savanna are found in limestone around Mt. Tapotchau on Saipan (Liske-Clark, 2015), which does not have the same problem of badland formation as found on Guam. On most islands in the Mariana archipelago, *Miscanthus* sp. is normally considered an indicator of volcanic soils, although on Saipan it is found in a few places on bare limestone (Mueller-Dombois and Fosberg, 1998).

Table 2 summarizes the acreage of savannas per island. Both Guam and Rota have savannas of primarily non-native invasive species.

Savannas throughout most of the Marianas are dominated by invasive species such as *Miscanthus floridulus*, which burns frequently. Savannas on Asuncion, Guguan and Saipan are dominated by native species. Although Saipan does have *Pennisetum polystachyon*, a nonnative species, it has not yet become dominant within the landscape (Figs. 6 and 7).

Sustainability

Ecotypes sustain through resiliency, redundancy, and representation. The viability of savanna ecotype depends on maintaining multiple and distributed ecotypes (redundant) of sufficient quality and size (resilient) with species richness and genetic range (representative) to survive across its ecological environment over time. Resilience is defined as the amount of disturbance that the system can absorb without a change in structure and composition (Holling, 1973; Carpenter et al., 2001). Disturbances include natural forces such as typhoons and droughts as well as anthropogenic forces such as wildfire or development. Redundancy refers to

Fig. 5 (continued).

Fig. 5 (continued).

the extent and range of an ecotype across a given landscape. Redundancy from having multiple resilient ecotypes can decrease the risk of loss. Ecotypes with few occurrences across the islands are less resilient to catastrophic events that might otherwise have a relatively minor impact on widely-distributed ecotypes (Stacey and Taper, 1992). Representative ecotypes are those not restricted to particular locations but are scattered throughout due to diverse species that can occupy various ecotypes.

Stressors

Climate Change

While climate change related stressors (e.g., increased precipitation, sea level rise, increased typhoon intensity and frequency) cause ongoing impacts, they are not currently a significant factor in the Mariana Islands. Climate-related stressors, such as typhoons, can have an impact on the savanna by causing erosion (Kerr, 2000).

Fig. 5 (continued).

Table 2 Savanna lands across the Mariana Islands (Reeves and Amidon, 2018).

Island	Area (Acres)	Area (% of Island)	Area (% of Marianas)

From Reeves and Amidon (2018). Savanna lands across the Mariana Islands.

Typhoons

The Mariana archipelago lies in a typhoon belt and is regularly exposed to typhoons. Typhoons cause a variety of impacts to vegetation including pruned or downed vegetation from intense wind, defoliation and damage from wind, heavy rain and salt spray, and mortality by salt water inundation in low-lying areas (Kerr, 2000). Typhoons impact savannas primarily by causing erosion of loosened soils, which expand badland areas.

Increase in typhoon frequency and/or intensity are one of the factors in the increasing development of badlands. A study by Scheman et al. (2002) indicated that badlands across the steepest slopes of the watershed contribute an average of 65.90 tons/

Fig. 6 Area of native and non-native dominated savanna and grassland in the Marianas. From Reeves, M.K. (2019). Savana and grasslands system quality summary.

Fig. 7 Amount of savanna and grasslands across the Mariana Islands. From Reeves, M.K. (2019). Savanna and grasslands area summary.

acre/year in soil yield. Scheman et al. concluded that the accelerated erosion of the soil and increasing badlands in southern Guam can be blamed on human disturbance.

Fires

The frequency of grassland fires during the dry season have been a serious ecological problem in the Mariana Islands since the arrival of humans (Minton, 2006). Many fires are deliberately started to clear land or to drive wildlife for hunters. Fires burn quickly in the savannas due to the high flammability of grasses and the density of the fuel load. According to the Pacific Fire Exchange, there are an average of 730 fires per year on Guam that burn 4800 acres (1942 ha). While fire can help maintain the savanna, increased frequency of fires can result in increased erosion, further preventing revegetation (Minton, 2006).

Drought

Drought has caused major ecological harm in the Mariana Islands. The dry season occurs annually from January through June, and during years immediately following an El Nino year severe dry seasons can cause drought (Lander, 2004). During this time, large stands of *Miscanthus* becomes fuel for wildfires.

Off-Road Vehicle Use

Recreational use of the savannas exacerbates erosion. Off-road vehicles, dirt bikes, mountain bikes, and large trucks criss-cross the mountains, digging up vegetation and loosening the topsoil. One of the most damaging stressors to the savannas on Guam is off-road vehicle use (Kottermair et al., 2011). Neither Saipan nor Rota experience this stressor as the savanna lands are too small for this kind of recreation. Off-road use, along with some hiking and mountain biking, can cause erosion by damaging vegetation and weakening root systems, loosening soil particles or by compacting the soil causing an increased surface bulk and reduced infiltration rate or rain (Kottermair et al., 2011) When enthusiasts veer off of established trails new bare areas form. Fig. 8 depicts a popular off-roading area.

Fig. 8 Photo of savanna land on Guam, showing erosion scars from off-roading activities. From (USFWS) U.S. Fish and Wildlife Service (2018). Photo of savanna land on Guam, showing erosion scars from off-roading activities. (USFWS unpubl. photo).

Table 3 Key invasives species of concern in the Mariana Islands which impact savanna systems.

Common name	Scientific name	Primary species affected	How invasive affects the habitat	Island impacted
Ants (Yellow Crazy Ant, Little Fire Ant) ^a	<i>Anoplolepis gracilipes</i> , LFA: <i>Wasmannia auropunctata</i>	Native fauna (birds, reptiles, mammals, arthropods)	LFA: Tend or protect plant pests such as aphids and scale	Guam, Rota, Saipan LFA: Guam
Scale insects (e.g., Asian Cycad scale, Cycad Blue Butterfly) ^b	<i>Aulacaspis yasumatsui</i> , <i>Chilades pandava</i>	<i>Cycas micronesica</i>	Feed on plant, infest root systems	Guam Rota
Feral ungulates (goats and pigs, deer, carabao) ^c	(<i>Capra hircus</i> , <i>Sus scrofa</i> , <i>Rusa marianna</i> , <i>Bubalus bubalis</i>)	All vegetation	Dig up and compact soils, facilitating erosion, consume or otherwise destroy natural resources, spread pest species	Guam, Rota, Saipan
Rodents (black rats) ^d	<i>Rattus rattus</i>	Native vegetation, prey on native and nonnative fauna, including birds	Prevent tree or grass re-growth, destroy grass seeds	All Islands

From (USFWS) U.S. Fish and Wildlife Service. (2018). Key Invasive species of concern in the Mariana Islands which impact savanna systems.

Invasive Species

Invasive ungulates such as deer, pigs, goats, and carabao increase rates of erosion through rooting and wallowing behaviors as well as by selectively preying upon native plants (Gawel et al., 2018). Also, the presence of ungulates on Guam attract both recreational and illegal hunting activities. Game trails created by hunters change the soil dynamics forming rills and possibly into an advanced stage called gully erosion. Table 3 describes impacts from invasive species on savanna systems in the Marianas.

Development

Development is a major factor negatively impacting savanna ecotype throughout the inhabited Mariana Islands. Most of the savanna lands on Saipan and Guam are located on volcanic slopes in the center of the islands (see Fig. 5). Increased housing demand has started to place development in the interiors of Guam and Saipan (ICF International, 2009). The Department of Defense holds large parcels of lands in the interior of Guam which include savanna. Continuing military development for training grounds, munitions storage, or personnel support facilities will convert savanna lands into developed lands.

Conservation Efforts

The Micronesia Challenge

In, 2006 the Republic of Palau, the Federated States of Micronesia, the Republic of the Marshall Islands, the U.S. territory of Guam, and the U.S. Commonwealth of the Northern Mariana Islands committed to conserve at least 30% of the near-shore marine resources and 20% of the terrestrial resources across Micronesia by 2020. This pledge has become known as the Micronesia Challenge. The Challenge aims to preserve these resources for the benefit of future generations, to sustain livelihoods, and to sustain each island's unique biodiversity (<http://www.micronesiachallenge.org>).

Examples of Micronesia Challenge projects in the Mariana Islands are described below.

- Rota's Talakhaya watershed, which contains areas of savanna has been revegetated with native grasses by local forestry staff. The staff is also educating local people on the fire impact to the savanna and how it can impact reef resources (Bickel and Mattos, 2015).
- On Saipan, the Laolao Bay watershed is being improved by revegetating badlands damaged by fire and illegal land clearings as well as conducting grassroots education campaigns (Bickel and Mattos, 2015).
- On Guam, the Humatak Project (Fig. 9), seeks to restore the watershed above Fouha Bay by implementing erosion control practices on the mountain slopes in the savannas and by educating the public about how erosion impacts coral reef resources. Sediment socks and vetiver grass (*Chrysopogon zizanioides*, a clumping grass species often used to stop erosion due to its thick root systems) were placed in areas displaying erosion and washouts. These erosion prevention measures resulted in both reduced erosion in the savanna and a reduction in reef sedimentation (Shelton and Richmond, 2016).

Several programs have been created to halt erosion in the savannas by replanting vegetation and covering badland areas with fiber mats to stimulate plant growth. Vetiver grass swales, trenches lined with grass, act as a soil trap and prevent soil transport. Fig. 9 shows the use of sediment traps on eroded slopes to stop soil loss. On Guam, the National Oceanic and Atmospheric

Fig. 9 Photo of Humåtak Project impacts on Guam's savannas in the Fouha Bay watershed. Image Courtesy of Austin Shelton, University of Guam Sea Grant.

Administration (NOAA) and the Center for Island Sustainability (CIS) have completed and ongoing projects to restore watersheds and coral health by stopping the spread of badlands in the savannas (NPS, 2017).

The CIS has also created initiatives to educate off-road motorists, bikers, and hikers about damages caused by improper use of trails and how this leads to badlands formation (Fig. 10). In 2018, a Guam-based Jeep dealer pledged to educate each new Jeep owner for responsible off-road use and an off-road adventure tour company pledged to encourage responsible use of trails. This program was announced at the Island Sustainability Conference in 2018 (Meno, 2018).

National Oceanic and Atmospheric Administration (NOAA)

NOAA's primary focus in the Marianas is on coral reef health, but as reef health is intertwined with upland health NOAA has created 10 Habitat Focus Areas (HFA) for watershed restoration to reduce erosion and runoff. On Guam, NOAA's HFA is the Manell-Geus watershed, which feeds into the southern lagoon. Restoration of the watershed has included replanting savannas with native vegetation, stopping erosion of badlands using fiber mats, and educating the public about responsible use of the land. National Oceanic and Atmospheric Administration partnered with Underwater World, the University of Guam, and Government of Guam agencies such as the Bureau of Statistics and Plans and the Department of Agriculture to complete the watershed restoration project. This project was created less than 2 years ago, and studies continue on its impacts to either the savanna or the reefs downstream.

Protected Lands

There are several protected areas found in the Marianas. These include conservation areas, national parks, critical habitat, a national wildlife refuge, and the only mitigation bank in the Pacific Islands. The Federal or local government designated these lands for the conservation of natural resources to protect them from development. Each area is regulated in regards to hunting, fishing, and other uses depending on the history and natural resources of area. The conservation areas in the CNMI are composed of all ecotypes aside from development but tend to prioritize forested areas (Liske-Clark, 2015).

Conservation lands in the CNMI comprise 22% of Rota, 4% of Tinian, and 9% of Saipan (Table 2 displays amounts of savanna ecotype). The entire islands of Guguan, Asuncion, Maug, and Uracas are protected by the CNMI constitution. The entire island of

Fig. 10 Severe erosion in Guam's savanna. (USFWS) U.S. Fish and Wildlife Service. Severe erosion in Guam's savanna. (USFWS unpublished photo).

Sarigan is owned by the Department of Public Lands but regulated by the Division of Fish and Wildlife. The CNMI conservation lands total 55.6 km² (21 mi²), representing 12% of the total land area. In the CNMI these lands are designated through the passage of a congressional bill and are under the ownership of the CNMI Department of Lands and Natural Resources or have been set aside by Department of Defense (DOD) to restrict activities permitted on the lands to minimize impacts to natural resources. On Guam, lands are placed under the ownership of the government of Guam or if they occur on DOD lands they remain under their ownership (Fig. 11) (Reeves and Amidon, 2018).

There are currently two national parks on Saipan and Guam. Both were designated to commemorate World War II and are comprised of primarily coastal ecotypes, although on Guam the National Park Service (NPS) has 688 acres (270 ha) of savanna in their Asan and Mt. Alifan units. These units are under the management of the NPS, which does basic vegetation management for the benefit of their visitors. There is a proposal under review by the NPS to designate a new park in Rota which may contain savanna lands but the status of that is unknown (NPS, 2017) (Fig. 12).

Critical habitat has been designated on Guam and Rota and contains some of the savanna ecotype. Critical habitat is defined as a specific geographic area that contains features essential for the conservation of a threatened or endangered species and that may require special management and protection. On Rota habitat was designated for the Mariana crow (Aga in Chamorro) and the Rota Bridled white-eye (Nosa Luta in Chamorro) and both are comprised primarily of forest habitat (see Fig. 13). Protection of designated critical habitat varies on land ownership.

In the CNMI, the Northern Mariana Islands Administrative Code (NMIAC) Chapter 65-30, § 65-30-101 details the permit requirements for any land clearing activities “to ensure no unauthorized clearing of any type of ecotype, including savanna, occurs in the CNMI.” Similarly on Guam, the Guam Administrative Rule (GAR) Chapter 3 Required Permits and Approvals under regulatory requirement 22 Guam Administrative Rules (GAR) 10,103, 10,106, 10,107 for any “development or construction activities that involve clearing, grading, filling, excavating, and other earth-moving operations.”

Protected Designations

Commonwealth of the Northern Mariana Islands Protected Lands

The government of the CNMI designated conservation lands located on the Sabana plateau and into the Talakhaya watershed in Rota in 1994 under local law 9-1. This land contains native forests, savannas (see Table 2 for acreage), coastlines, and coral reefs. All forms of take (meaning harassment or harm, including harvesting or hunting) of wildlife or plant life is prohibited, with the exception of traditional healing plants.

Government of Guam Protected Lands

In 2004 the Government of Guam proposed a GovGuam Critical Habitat Alternative to the USFWS (DAWR, 2006). The stated objective was to establish four areas for the conservation of natural resources. The proposed areas were Anao (695 acres), Asdonlucas (471 acres), Cotal (552 acres), and Bolanos (2830 acres). Anao is primarily native limestone and secondary forest. Cotal is primarily savanna, badlands, and some secondary forests. Bolanos consists of savanna and forest. Asdonlucas was originally native limestone forest, but the area was leased to a private entity and has now become the Guam Raceway. Although the lands are all treated as conservation lands by the state wildlife agency, there are no binding legal protections for these lands. Cotal, which is primarily savanna ecotype, has had several acres removed for the construction of an experimental wind turbine by the Guam Power Authority. If successful, several more turbines may be built within the conservation area (Dumont-ol Daleno, 2016).

Stakeholder Engagement

Various awareness and engagement activities have been and/or are being undertaken to improve stakeholder engagement in reducing impacts from invasive species and reducing the threat from new species arriving and establishing. Existing efforts are mostly conducted by individual offices for specific activities and/or pest organisms. The University of Guam's CIS has worked with Jeep dealerships to educate buyers of the damages caused by off-road vehicle use (Meno, 2018). SeaGrant has worked with some villages in southern Guam to educate hunters of damage caused to the savanna by burning lands for hunting and how that causes damage to reefs (University of Guam Sea Grant Program, 2017). Guam Department of Agriculture, University of Guam, the Northern Marianas College as well as numerous others have all supported awareness activities.

Interactions of All the Above

The primary stressors to savannas include development activities and badland formations. These stressors are significant and ongoing, act in concert with other stressors, and are expected to continue or increase in magnitude and intensity into the future without effective management actions to control or eradicate them. Current conservation efforts taken by Federal, State, private, and agency partnerships combined with certain laws and regulations limit some of the effects of the stressors on the ecotype, but do not eliminate them. The stressors continue to contribute to the further increase of development and loss of species diversity. Development within the savannas is concentrated in southern Guam. The native plant and animal species have experienced reductions in numbers while invasive plants and animals take over. Without active management, badlands will continue to spread in the savannas of southern Guam.

Efforts to combat erosion have increased recently as part of an effort to protect the coral reefs. The protection of the savanna is not the primary reason for these restoration projects, but is necessary for protection of the reefs. Public education campaigns have periodically occurred to educate hunters and people who recreate off-road of how their activities cause erosion. Projects to prevent erosion by planting trees or laying vetiver swales must be maintained for a period of years, however, often once the trees are in the ground they are not monitored nor maintained. For any erosion control project to be successful on a long-term basis there should be monitoring and remediation for several years at least. This is not currently happening. While erosion control projects have had some protective effect on the savannas, large planned developments still threaten this ecotype.

Ecotypes in the Mariana Islands are experiencing stress from multiple sources. Many stressors are intertwined with each other. For example, increases in dry season severity can lead to increases in wildfires. Increases in development will require importation of more construction materials, leading to the potential for the introduction of more invasive species. Some stressors are beyond the ability of humans to control. Typhoons and volcanic eruptions will occur no matter what, and so it is important to ensure that ecotypes are as resilient as possible to bounce back from stochastic events.

The ultimate fate of savanna lands on each island will mainly depend upon its ownership. Savanna lands in protected areas, such as refuges or restricted-entry islands, will remain savanna due to the conservation missions of the owners. Savanna lands that are privately owned are more likely to be developed. See Table 4 for a chart of land ownership on each island.

In summary, the savanna across Marianas is highly resilient (Table 5) due to its ability to recover from disruptions such as fires or typhoons. Many grass species can regrow quickly from roots. Fire is not just a disruptor, but helps to maintain the savanna by preventing large trees from gaining a foothold. Savanna is highly redundant due to being present on 11 of the islands in the chain. A loss of savanna on one island may not be detrimental to the overall savanna across the Marianas and may be recovered because of the presence on other islands. Savanna ecotypes have medium representation due to the moderate diversity of grass, herb, and fern species present.

In the following sections we analyze future scenarios and their possible impacts for conservation in the Marianas.

Future Scenarios

The condition of savanna and grassland in the foreseeable future is based on potential changes in three conservation management parameters (CMPs). These conservation parameters capture the social and legal mechanisms under which natural resource conservation is carried out. The CMPs are as follows:

Table 4 Savanna land ownership by island.

<i>Island</i>	<i>Land Ownership^a</i>	<i>Area (Acres)</i>	<i>Area (% of Island)</i>	<i>Area (% of Marianas Islands)</i>
Agrihan	Public	5357	43	2
Alamagan	Public	1530	39	1
Anatahan	Public	3678	38	1
Asuncion	Public	918	36	<1
Guam	Federal DoD	1453	1	1
	Federal NPS	335	<1	<1
	Private	8296	6	3
	Public	5316	4	2
	Unknown ^b	6371	4	2
Guguan	Public	392	26	<1
Pagan	Public	2928	21	1
Rota	Private	26	<1	<1
	Public	199	1	<1
	Unknown	<1	<1	<1
Saipan	Private	286	1	<1
	Public	907	3	<1
	Public Homestead	1	<1	<1
Sarigan	Public	341	21	<1

^aPublic land includes homesteads (Public lands proposed for either village or agriculture homesteads), and lands in the CNMI leased to developers. DoD lands include lands owned by DoD and lands DoD leased and leased back to farmers on Tinian. NPS lands include lands owned by the NPS on Guam and leased by NPS on Saipan. USFWS is refuge land.

^bUnknown lands on Guam, Rota, and Tinian are lands with no associated GIS data layers for the determination of ownership. Most probably ownership is a combination of local government and privately owned lands.

Table 5 Levels of resiliency, redundancy, and representation for savanna habitats that exist in the Marianas.

<i>Resilience</i>	<i>Redundancy</i>	<i>Representation</i>
High	High	Medium

Savanna and Grassland Habitat Status Assessment for the Mariana Islands.

From (USFWS) U.S. Fish and Wildlife Service. Levels of resiliency, redundancy, and representation for savanna habitats that exist in the Marianas.

- (1) *Conservation values*: Stakeholder involvement and public opinion determine the formulation, implementation and funding of natural resource conservation within laws and development plans.
- (2) *Laws and biosecurity*: National, state, county, and city laws and regulations are the means by which natural resource conservation and biosecurity are supported and implemented. (e.g., hunting regulations, Clean Water Act, Endangered Species Act, and local laws, etc.).
- (3) *Development or conservation planning*: National, state, county, city, and private development plans or conservation plans define specific actions that result in losses or gains in natural resource conservation and biosecurity (impacts are only realized at the time of implementation).

These conservation management parameters are critical factors that drive the direction and magnitude of natural resource conservation, and determine foreseeable future scenarios. The year 2035 is the extent of the “foreseeable future,” and is based on the projected divergence of IPCC Representative Concentration Pathway (RCP) climate change scenarios (van Vuuren et al., 2011; Miller, 2018).

The four foreseeable future scenarios considered in this assessment are:

Future Scenario One, Status Quo—The most likely foreseeable future; no change in natural resource conservation in the CMPs, so the current rate of change in land cover continues through the foreseeable future.

Future Scenario Two—A slight increase in natural resource conservation in the CMPs marginally improves conservation management.

Future Scenario Three—A slight to moderate decrease in conservation actions in the CMPs substantially decreases conservation management.

Future Scenario Four—A moderate to large increase in conservation actions in the CMPs substantially improves conservation management.

The future condition of savanna and grassland ecotypes in Scenario One, the status quo, was characterized from an assessment of change over time in savanna and grassland land cover obtained from existing land cover maps (Amidon and Reeves, 2018). Based on these land cover maps, an annual rate of change for savanna and grassland ecotypes was estimated, and a projected change (in acres/hectares) was calculated for the year 2035. The resulting information on changes in land cover by 2035, as derived from existing land cover change estimates, is the extent of the savanna and grassland ecotype that is expected in the foreseeable future under Scenario One, the status quo, where conservation efforts remain unchanged and the current rate of change in land cover is also unchanged.

The future conditions of savanna and grassland ecotypes for Scenarios Two, Three, and Four cannot be quantitatively (acres/hectares) estimated. However, the Scenario One estimate can provide a “baseline” for a qualitative characterization of changes in the future condition of savanna and grassland ecotypes under Scenarios Two, Three, and Four.

Changes in human population are captured only by the changes in the “developed” land cover footprint derived from land cover map analysis (Amidon and Reeves, 2018). Impacts from other sources of human activities or human-caused stressors (e.g., plant and animal diseases, wildfires, invasive species, etc.) are not well characterized in the land cover changes, but significantly contribute to increases in the land cover area dominated by non-native vegetation.

Also, note that island-wide implementation of the CMPs is unlikely to have a significant effect on climate-related stressors (temperature, precipitation, and severe weather) resulting from global warming by 2035. This lack of CMP climate effects is due to the global lag in climate response to changes in greenhouse gas emissions which occurs on the order of centuries rather than years (Solomon et al., 2009; Gillett and Cullen, 2011; Jevrejeva et al., 2012). Evidence of climate effects is also confounded by the large annual variation in the Pacific islands climate parameters, which is much greater than projected climate change by 2035. Although impacts from climate-related stressors do not change across the four scenarios, they were included in this analysis because of their overall magnitude of potential importance to future ecotype viability.

Future Scenario One, Status Quo

Summary: Scenario One is considered the most likely future scenario, and serves as a “baseline” for comparing among the four future scenarios. There is no change in the implementation of the three CMPs between 2018 and 2035. A continuing current rate of change in land cover through this foreseeable future results in a slow but continuous change in the ecotype as described below.

Description: Using the current rate of change, the land cover for savanna was calculated for the year 2035. The projected change in land cover by 2035 is the only future scenario with quantitative values (acres or hectares). The anticipated changes, under Scenario One, for each of the ecotype stressors affecting savanna ecotype are given in Table 6.

An expanding human population and increased development and general land use on all inhabited islands is anticipated (Amidon, 2018; Amidon and Reeves, 2018), and therefore ecotype stressors are expected to increase at a small annual rate. Exceptions are a small to moderate annual rate of increase for development, wildfires, and surface air temperature, and a small annual rate of decrease for precipitation. On average, the percentage of land developed for residential, commercial, and agricultural purposes on the inhabited islands is expected to increase by 25% from 2016 to 2035. This rate is only true for the southern inhabited islands of Guam, Rota, Tinian, and Saipan. Data on rates of development for the remaining islands does not exist at this time. By island, estimated rates of change in savanna ecotype from 2016 to 2035 are: Guam – 1%, Rota 166%, Tinian 0%, and Saipan – 16%.

On Guam, off-roading is expected to continue to degrade the savanna, causing erosion and the spread of badlands. Current levels of typhoon events are not expected to impact savannas. Incidences of fires may remain at their current rate.

The island of Rota has seen a decrease in the human population (U.S. Census Bureau, 2010), most probably due to the collapse of the tourism industry. Farmlands and ranches have been abandoned and allowed to return to their natural state.

A few small conservation actions currently in place may slow the rates of erosion from small areas, but overall there will be a steadily increasing amount of erosion from the savannas on Guam and Saipan. Conservation will continue as small projects with a limited scale producing a limited overall benefit.

Because the Scenario One biosecurity CMP remains unchanged while the population and development continue to grow, an increased potential for new invasive species and new diseases (particularly those affecting native plants) exists. The introduction of additional plant diseases and invasive species may enhance the conditions that support wildfires.

Future Scenario Two—There is a slight increase in the CMPs that marginally improves conservation management.

Summary: Conservation Agencies and stakeholders work with increased but limited resources to slow or stop the degradation of landscape areas.

Description: Scenario Two is essentially “status quo” with minor improvements in the three CMPs. The anticipated changes, under Scenario Two, for each of important ecotype stressors for savanna are given in Table 6.

Though there is an expanding human population in Scenario Two, development is not expected to substantially increase. A slightly improved biosecurity effort should help reduce invasive species and plant diseases but increases are still expected. The small increased support of natural resource management in the CMPs is not expected to greatly alter wildfire frequency and intensity, but these might (lower slightly) compared to Scenario One. The CMP supported conservation will not prevent, mitigate, or reverse the impacts of climate change-related stressors.

The main stressor to savanna across the archipelago is development, which may see some controls in place to encourage development in existing cleared areas. Savannas on Guam may receive more conservation attention if outreach for damage due to off-roading is expanded.

Future Scenario Three—There is a small to moderate decrease in conservation actions in the CMPs that substantially decreases conservation management,

Summary: All natural resource management actions in the CMPs are set aside in deference to land use for economic development. With extensive localized management, some native species may persist in park-like settings or in areas where land development is not possible.

Description: Scenario Three has substantial declines in natural resource conservation within the three CMPs. An increasing human population is supported in its use of land for economic development over the conservation of native ecotypes. Areas that cannot

Table 6 Responses of Savanna and Grassland habitat stressors in foreseeable future scenarios.

Conservation Management Parameters (CMPs)				
Conservation values	Stakeholder involvement and public opinion influence the formulation, implementation, and funding of natural resource conservation and biosecurity (NRC/B) within laws and development or conservation plans			
Laws and Biosecurity	National, state, county, and city laws and regulations are the means by which NRC/B are supported and implemented			
Planning for Development or Conservation	National, state, county, city, and private development plans or conservation plans define actions that result in losses or gains in NRC/B (impacts realized at implementation)			
Foreseeable Future Scenarios and the resulting Savanna and Grassland habitat conditions				
Use Foreseeable Future Scenario One as a “baseline” to characterize changes in Conservation Actions and Habitat Conditions in Future Scenarios Two, Three and Four	Scenario One: CMPs: Unchanged in support for NRC/B Conservation Actions: No change; current rate of land cover change continues through the foreseeable future Habitat Condition: Habitat area, quality, and sustainability slowly decrease through the foreseeable future	Scenario Two: CMPs: Small increase in support for NRC/B Conservation Actions: Marginal increase Habitat Condition: Habitat area is unchanged through the foreseeable future; habitat quality and sustainability are slightly enhanced through the foreseeable future	Scenario Three: CMPs: small to moderate decrease in support for NRC/B Conservation Actions: Substantial decrease. Habitat Condition: Urban and agricultural uses are prioritized over conservation; habitat area, quality, and sustainability substantially decrease through the foreseeable future	Scenario Four: CMPs: Moderate to large increase in support for NRC/B Conservation Actions: Substantial increase. Habitat Condition: Robust, sustained effort to restore, manage, and expand conservation; habitat area, quality, and sustainability substantially increase through the foreseeable future
Habitat Stressors	Responses of Savanna and Grassland habitat stressors			
Development	Small to moderate increase	No change (redevelop)	Moderate to large increase	Small to moderate decrease
Altered hydrology	No change to small increase	No change	Larger increase	Small decrease
Recreation/access	Small increase	Small increase	Larger increase	Larger increase
Invasive species	Small increase	Small increase	Larger increase	Small decrease
Plant diseases	Small increase	Small increase	Larger increase	No change to small decrease
Fire	Small to moderate increase	Small increase	Larger increase	No change to small decrease
Erosion	Small increase	No change	Larger increase	Small decrease

From (USFWS) U.S. Fish and Wildlife Service. Responses of savanna and grassland habitat stressors in foreseeable future scenarios.

support development become the only areas of free-living native species. The anticipated changes, under Scenario Three, for each of the stressors important to savanna are given in [Table 6](#).

An expanding human population requires increased land use for agriculture and development with no encumbrance from natural resource management. Biosecurity controls are significantly weakened in this Scenario leading to an increase in invasive species problems and new plant diseases. Combined together, these factors will result in substantial increases of wildfire frequency and extent. The substantial loss of CMP supported conservation may locally aggravate the impacts of climate change-related stressors.

Future Scenario Four—There is a moderate to large increase in conservation actions in the CMPs that substantially improves conservation management.

Summary: An overt and robust, active, ongoing effort is made to engage partners and stakeholders in identifying and prioritizing landscape areas needed for the conservation of native ecosystems, and to actively restore and expand these areas.

Description: A substantial emphasis on natural resource conservation is present in the three CMPs, reflecting increased societal concern for declines in natural ecotypes and biodiversity. Active and well-supported natural resource management begins to restore these ecosystems and expand their landscape areas. The anticipated changes, under Scenario Four, for each of the ecotype stressors important for savanna are given in [Table 6](#).

The needs of an expanding human population are addressed through more efficient land use governance based on redevelopment rather than development of undeveloped areas. Modern and novel agricultural practices focus on those that do not affect existing natural areas or areas needed for native ecotype restoration. Substantially improved biosecurity regulations decrease introductions of invasive species and plant diseases. These improved land management actions result in decreased wildfire frequency and extent. The substantial increase in CMP supported conservation may locally mitigate the effects of climate change-related stressors, but climate change is expected to continue.

On Guam and Saipan, development is controlled. Durable conservation areas are created which then undergo enhancement to remove invasive plants and animals, returning the ecotype to its original state. Wildfires are no longer intentionally set and badland areas are reduced. Feral ungulates are controlled and no longer create wallows, ruts, or rubs on vegetation.

Conclusion

Conservation efforts by Federal, State, and private entities and agency partnerships have limited some of the effects of the stressors on savanna in the Marianas, but have not eliminated them. A stronger effort to engage partners and stakeholders in identifying and prioritizing landscape areas required for the conservation of native ecosystems, and to actively restore and expand these areas is needed for the successful conservation of savannas.

The primary stressors to savannas include development, invasive species, erosion caused by recreational off-road vehicle use, fires, typhoons and drought. Despite some protected areas and active management efforts to target stressors, they are expected to continue or increase in magnitude and intensity in the future. It is likely that without a greater shift in land ownership by refuges or other owners with a mission of conservation, and without an increase in active management to provide long-term monitoring and remediation, savanna in the Marianas will continue to be degraded or destroyed in the future.

Glossary

Freshwater: A Glossary of Terminology Used in Freshwater Biology and Management (Suring, 2020d).

The definitions of terminology used to describe the ecological relationships and management of freshwater systems may vary

by geographical region and professional field of endeavor. This glossary of more than 220 terms used in reference to freshwater is provided to establish a common base of understanding among workers in this discipline.

Abstract

The freshwater biome is an essential life-sustaining element for the Earth which cannot be substituted for. Freshwater is indispensable for humans; water scarcity currently endangers food production throughout the Earth. It is also the foundation for substantial biological diversity and critical ecosystem functions. This review of the Freshwater Biome established the importance of freshwater to human life and enterprise by discussing the major uses of freshwater, including ecosystem services. We then provided an overview of the ecosystems that make up the Freshwater Biome, some elements of biogeography of the Freshwater Biome, and offered insights to the conservation and management of water resources in the Biome.

Introduction

The freshwater biome is an essential life-sustaining element for the Earth which cannot be substituted for (Koehler, 2008). Freshwater is indispensable for humans; water scarcity currently endangers food production throughout the Earth. It is also the foundation for substantial biological diversity and critical ecosystem functions. Over 10,000 fish species occur in freshwater (Lundberg et al., 2000) and when amphibians, aquatic reptiles, and mammals are included, perhaps as much as one third of all vertebrate species are associated with freshwater. When invertebrates are also considered, more than 10% of the described species on Earth occur in freshwater. Considering that surface freshwater contains about 0.01% of the Earth's water and covers only about 0.8% of the Earth's surface (Gleick, 1996), freshwater truly is an oasis of life.

Freshwater is a limited resource that is under significant anthropogenic threat. Ecosystems in the Freshwater Biome may be the most endangered ecosystems on Earth (Dudgeon et al., 2006). Indicators are revealing rapid population declines and a large extinction risk in freshwater organisms (Reid et al., 2019).

This review of the Freshwater Biome established the importance of freshwater to human life and enterprise by discussing the major uses of freshwater, including ecosystem services. We then provided an overview of the ecosystems that make up the Freshwater Biome using the basic classification system described by Fisher (2018) (i.e., lentic—still waters, lotic—flowing waters, riparian, aquifer/groundwater, glaciers). We used the established definition of freshwater (i.e., water that contains less than 1000 mg/L of dissolved solids [United States Geological Survey, 2019]) to guide what waters we included in this review. As such, we did not include brackish waters, estuaries, and mineral springs. We also only included natural water bodies, so we did not address water bodies created by human activity, such as reservoirs, stock ponds, canals, irrigation ditches, or rice paddies (Smith et al., 2002).

We provided a brief overview of some elements of biogeography of the Freshwater Biome and offered insights to the conservation and management of water resources in the Biome. We concluded with a glossary of terms associated with freshwater.

Why is Freshwater Important?

The Importance of Freshwater for Domestic Use (Padowski, 2020)

Of the many uses humans have for freshwater, water for domestic use is the most intimately understood by any given individual because it is the water we use each day. Domestic use includes all the water used in and around the home including water for indoor use, such as drinking, bathing, cleaning, preparing food, and outdoor use, such as maintaining lawns, livestock, and gardens. Due to its importance, understanding where and how much water is needed for domestic use continues to be a high priority for communities around the world. This is particularly true as rapid growth is expected to push the world population to 9.7 billion people by 2050. In most cases, this urban growth will occur in urban areas, and therefore particular attention is paid to the challenges and opportunities for meeting domestic water demands in urban areas. This article explores the importance of freshwater for meeting domestic use purposes in an increasingly human-dominated world. Included is an overview of how water for domestic purposes is used around the world, how domestic use impacts the freshwater resources that support communities, what the challenges and opportunities we as a society face as water becomes a more precious resource.

Importance of Freshwater for Irrigation (Edwards and Nehra, 2020)

The use of freshwater in irrigation arose in the world's first civilizations and remains critical to the planet's food supply today. This article first provides some historical context for irrigation before tackling the question of competing demands for water, discussing how coordination among irrigators is achieved and the complex relationship between irrigation and water conservation and reuse. The discussion focuses on four countries—the United States, India, China, and Chile—which provide insight into the importance of irrigation, as well as current challenges.

Importance of Freshwater for Livestock (El Mahdy, 2020)

Of the freshwater (blue footprint water) from rivers, lakes and groundwater 33–88%, is directed towards agriculture in varying proportions depending on the area. Only 0.6% is used for direct consumption by livestock or indirect activities associated with livestock. The distribution of livestock on the globe is dependent on existing water and the ability of animals to tolerate water deficiency and quality. In the animal body, water has multiple functions: metabolic, growth, breeding, and production. Deprivation or deficiency of freshwater affect these functions, but species from arid and semiarid areas have developed adaptations to these conditions. There are large differences between water requirements, for livestock in semi-arid and arid area of extensive and pastoral system, compared to livestock in the intensive farming system.

Dependent on the farming system, the type of rainfed agriculture and the distance to water source, the watering frequency is different. Water quality in many regions is poor in terms of salinity and contamination with toxic elements. In arid and semi-arid areas, water usually has a large amount of chloride, which is why research is directed to choosing the most resistant species to low quality water and to develop farms in these areas as well.

Importance of the Conservation and Management of Freshwater to Aquaculture (Goddard and Delghandi, 2020)

Inland fish farming contributes to the nutrition and livelihoods of many millions of people. Most fish are grown in constructed ponds or floating cages in natural or man-made water bodies. Freshwater fish farming is often integrated with the farming of crops, where wastes and by-products from one component are used as inputs for another. Developing technologies offer new opportunities to conserve water and increase the productivity of freshwater aquaculture.

Recirculating aquaculture systems (RAS) have been developed with the potential to greatly reduce the water requirements and environmental impacts of fish farms. Biofloc technologies (BT) utilize in situ bacterial processes to maintain water quality and provide food for filter-feeding species of fish and crustaceans. Full integration of fish and vegetable production can be achieved through aquaponics, which combines aquaculture and hydroponic plant production within a recycled water system. This article reviews current developments in water recirculation techniques, biofloc technology, and aquaponics against the background of increasing food security needs and water resource issues.

Mining and Water Resources (Mudd, 2020)

This article reviews the basics of mining and its interaction with water resources. While mining often requires a large amount of water, it can also present various risks to water resources, such as depletion or pollution (especially if acid and metalliferous drainage related to iron sulfide minerals occurs to the surface environment). Modern mining is typically regulated to address these risks, with statutory environmental reporting increasingly being made public to improve transparency and align with the need for industry-wide reporting on sustainable development performance. The article presents a concise overview of mining, its interactions with water resources, key risks to manage, and the principal regulatory and reporting approaches which can be used for sustainable management of both mining and water resources.

Freshwater and Industries (du Plessis, 2020)

Industries require large amounts of water which are used by various industries around the world at different rates and in different ways. Global water consumption has consistently been increasing since the 1980s and is expected to continue due to rising demands. Currently industrial water consumption is described as a major drain on the world's limited water supply and it is expected that the water demand will exceed current supply by 40% by 2030. The use of water for industrial processes as well as the discarding of wastewater can have various impacts if not properly managed and controlled.

The continued increase of industrial water use accompanied by continued population and socio-economic growth will consequently exacerbate current effects of industrial water use and cause greater future challenges. Industries are a huge source of pollution around the world as they produce pollutants which can be very harmful to both the environment and the human population. Freshwater resources around the world are faced with significant pollution problems, some more than others. The expanding industrial base with accompanied pollution have placed additional pressure on existing water and often causes water resources to no longer be suitable for human consumption or other uses. Water is at increased risk worldwide and industrial sectors will have to implement various strategies to minimize this risk in the future.

Importance of Freshwater for Electric Power Generation (Liao, 2020)

Global electric power generation relies heavily on water. Hydropower utilizes the potential and kinetic energy in running water and thermoelectric power plants, e.g., coal-fired, gas-fired and concentrated solar power, withdraw significant volumes of water for cooling purposes. Water is also used in various other stages of electric power generation's life cycle, such as coal mining, transportation, crop irrigation, and so forth. Consequently, water shortages and rising water temperature can lead to curtailment of electric power generations.

Climate change is expected to deteriorate water scarcities in some regions, which, compounded with rising water temperature, can exaggerate such electric power generation's water-related risks. Adopting air cooling systems, transforming the energy portfolio to gas, solar PV and wind, and utilizing alternative water sources, e.g., seawater and reclaimed water, can help reduce the electric power generation's reliance on freshwater resources in order to cope with future potential water-related risks.

The Importance of Freshwater for Providing Ecosystem Services (Apostolaki et al., 2020)

Freshwater ecosystems, whether surface, groundwater, or in the form of ice caps are fundamental for human life and for supporting the vast biodiversity, natural processes, and cycling. They provide ecosystem services, thus, benefits for humans and their societies obtained from nature, in all four categories: provisioning, regulating, cultural and supporting. The importance of sustaining ecosystem integrity via protecting ecosystem services is undeniable. However, it will be a big challenge as long as the human-induced degradation of the natural environment continues.

Lentic Freshwater

Ephemeral Wetlands (Deil, 2020)

Ephemeral wetlands (EW) are habitats with seasonal water body and ephemeral plant cover. Subtypes are shorelines of permanent rivers with fluctuating water level, seasonal pools in climates with variations in rainfall, and the ephemeral flush habitat on inselbergs. EW offer extreme environments, shifting from flooding to water shortage. Short-lived annuals, dwarfish perennials, and resurrection plants find a niche there. A permanent seed bank (and egg bank for crustaceans) buffers the year-to-year variability. Strong selective forces result in evolutionary processes like convergence, niche constancy, endemism, and vicariance of taxa. By sheltering rare and endemic species, EW are jewels of biodiversity.

Wetlands (Campbell, 2020)

Wetlands are globally diverse ecosystems that occur between terrestrial and aquatic environments. The degree of flooding is the main control on wetland vegetation, which varies from shallow water wetlands with submerged and floating-leaved plants, to emergent marsh, and treed swamp. Wetlands support unique flora and fauna, from duckweed to mangrove trees and from frogs to hippopotamus. Humans exploit them for water, rice, and fish, but wetlands also provide key services, such as flood attenuation, coastline protection, water purification, and carbon regulation. Despite these benefits, humans have drained or converted over half of global wetlands. Extensive wetlands remain, but many are threatened by altered flooding regimes, invasive species, nutrient enrichment, contamination, and climate change. Conservation efforts must focus on protecting wetlands and especially on maintaining key ecological processes on which wetlands rely.

Ponds (Lemmens and Pinceel, 2020)

Ponds are abundant landscape elements that provide vital ecosystem services and contribute disproportionately to biodiversity. Despite their importance for human society, they are threatened habitats and their protection and conservation is often neglected in current national and international legislation. We summarize a number of key aspects on pond ecology and biodiversity. In addition, we discuss current policy and highlight essential elements for the effective conservation of ponds.

Lakes (Suring, 2020a)

There are approximately 304 million freshwater lakes world-wide with the highest concentration, area, and perimeter of lakes located within boreal and arctic latitudes. The seven main formation processes of lakes are tectonic activity, volcanic activity, glacial activity, fluvial action, Aeolic action, anthropogenic action, and marine action. Lakes are generally characterized by low flow velocity and relatively low inflows and outflows. The primary parameters used to describe geomorphologic characteristics include lake length, lake width, lake depth, direction of major axis, shoreline length, lake area, lake volume, insulosity, and watershed to lake area/volume. Approximately 45% of photosynthesis on earth occurs in aquatic environments and photosynthesis supplies the primary source of organic matter for the growth and metabolic demand of all organisms in lakes.

Cultural eutrophication is thought to be the most widespread stressor of habitat in natural lakes. After eutrophication, acidification is the most important threat and stress factor for lake habitats. Above all, aquatic ecosystems are very vulnerable to climate change which influences the physical, chemical, and biological structure of lakes. These influences include fluctuating water levels, increased water temperature, shorter ice-cover periods, invasion of nonindigenous animal and plant species from tropical and subtropical regions, and structural changes in catchment areas.

The value of biological diversity in freshwater lakes and the need for its conservation is becoming more important world-wide. However, the challenges involved with the conservation of freshwater lakes are great. It is often difficult to decide what management

action to implement and what will be most effective. However, positive conservation action has brought real and sustained benefits across scales, from local to global, via a variety of mechanisms.

Lotic Freshwater

Springs (Suring, 2020b)

Springs are a unique resource from an ecological, economic, and cultural perspective. Springs harbor highly specialized and regionally restricted flora and fauna, often resulting in a unique freshwater biological diversity. Springs serve as evolutionary refugia, supporting concentrations of relict and endemic species that require habitat stability. Springs also provide a source of freshwater for personal human use and commercial sales. Major threats to springs include human draining and diversion of groundwater sources, pollution, habitat alteration, and invasive species. Moreover, restoration efforts are expensive and ecological responses to restoration are largely unknown. The safest management strategy is to refrain from potentially harmful land use within the vicinity of springs.

Stream Biomes of the World (McManamay and Jager, 2020)

Streams comprise only a small portion of Earth's terrestrial land surface area yet harbor a significant amount of the world's biodiversity. These ecosystems also support many competing human societal services, predisposing them to intense ecosystem alteration and leaving very a small percentage of streams in their natural state. Given their rarity and propensity for human disturbance, understanding stream structure and function, and how to conserve those properties, is extremely important. This article provides an overview of stream environments, their form and function, the organisms that inhabit them, and major ecological concepts and paradigms. An overview of major types of commercial uses is provided, which correlates with major anthropogenic stressors and the nature of ecosystem alteration. Finally, the article concludes with approaches and strategies for stream conservation and management.

Rivers (Wohl et al., 2020)

Ecosystems associated with rivers are intricately connected to their entire watershed. The river ecosystem includes the channel of active water flow, floodplain, and riparian and hyporheic zones. This ecosystem is shaped by interactions among the natural flow of water, sediments within the river and entering the river, and large wood regimes within the riparian zone. River integrity describes the ability of a river ecosystem to adjust to changes in these elements and through these adjustments maintain the habitat, disturbance regime, and connectivity necessary to sustain native biotic communities. Riverine food webs conceptualize the coupling between the physical environment and biotic communities and can be used to examine recovery from disturbance, variation in the structure of communities, and sources of energy that fuel metabolism within the ecosystem.

Riparian

Riparian Ecosystems (Capon, 2020)

Riparian ecosystems encompass a diverse suite of ecosystem types, including river banks, floodplains and wetlands, which are characterized primarily by being ecotones, or transitional zones, between adjacent terrestrial and aquatic realms. In general, riparian ecosystems represent wetter, cooler, and more heterogeneous habitats than adjacent upland areas and consequently tend to support biologically distinctive, productive, and diverse communities. Riparian ecosystems also provide a wealth of critical ecosystem functions and services of importance at local and catchment scales.

In particular, riparian vegetation plays a key role in: regulating microclimates and water quality; preventing riverbank erosion and promoting landform stability; subsidizing aquatic and terrestrial food webs; and providing habitat for a wide range of aquatic, amphibious, and terrestrial organisms. Despite these values, riparian ecosystems are also some of the most altered, degraded, and vulnerable ecosystems on Earth, due largely to their position in the landscape and hotspots of intensive human activity.

Effective management and restoration of riparian ecosystems is increasingly urgent, for both the conservation of much terrestrial and aquatic biota and the wellbeing and livelihoods of people throughout the world. Management approaches range from protection of intact riparian ecosystems to active revegetation of degraded riparian zones. Significant knowledge gaps exist in many places, however, regarding relationships between riparian ecosystem structure and function and the responses of these to disturbances and management interventions.

Groundwater and Aquifers

Groundwater and Aquifers (Suring, 2020c)

Groundwater and associated aquifers are considered essential resources for the maintenance of human life. However, the quality of groundwater and recharge rates has been diminished in many areas of the world. This poses a real threat to the health of aquifers and groundwater-dependent ecosystems such as springs, wetlands, streams, rivers, and lakes and the economies they support. Hydrological recharge of aquifers is complex and is affected by climate, geology, soil type, vegetation, and land use. Managers are becoming increasingly aware that aquifers are dynamic ecosystems rather than just water stored underground and that we need to identify and manage for the environmental values associated with groundwater. Sustainable groundwater management will allow groundwater to be maintained for an indefinite time without having unacceptable environmental, economic, or social consequences.

Glaciers and Ice Sheets

Glaciers and Ice Sheets (DeBeer et al., 2020)

Glaciers and ice sheets are masses of ice and snow that persist over many years formed by the accumulation and compaction of snow. They cover a significant amount of the Earth's land surface and store most of the world's freshwater. Glaciers flow under their own weight, carving out landscapes and transporting sediment and rocks as they move, and they advance and retreat in response to changes in the mass balance, or difference between annual accumulation and ablation.

Glaciers and glacierized river basins have unique hydrological characteristics. They serve as an important store of freshwater and influence the characteristics of annual and seasonal runoff downstream. Glaciers and ice sheets also represent an important biome with a rich diversity of life, from microbial communities to microscopic organisms and macroinvertebrates, and they influence ecosystem functioning well beyond their margins and termini. In recent decades, most glaciers worldwide have been losing mass and retreating in response to climatic variations, now primarily driven by human activity. The Greenland and Antarctic Ice Sheets have also begun to lose significant amount of mass and have exhibited an accelerating pattern of loss. This is expected to continue for many decades or more under current and expected future climate conditions, with the loss of much of the world's mountain glaciers, and significant changes in polar ice caps and ice sheets.

The loss of glaciers and ice sheets poses many problems and challenges, including sea level rise implications, regional changes in water availability, impacts on glacial and downstream ecosystems, release of legacy contaminants stored on and within glaciers, glacier-related hazards, feedback effects on regional and global climate, and many others that affect the well-being of people and communities. There is a need for more observations, better understanding and prediction of glacier dynamics, coordinated adaptation and mitigation strategies across multiple levels from local to international, and a coupled systems approach that integrates physical dimensions of changing ice environments with the human systems that engage with or depend upon them.

Biogeography

The Subtropical Everglades, Florida, USA (Sklar et al., 2020)

Everglades' restoration, the largest of its kind in the world, is expected to restore ecosystem functionality and community structure. Anthropogenic changes in peat elevations, water quality, hydrology, and habitat loss can make plant and animal recovery difficult. However, our understanding of the complexity of Everglades ecology and the spatial and temporal scales associated with plant and animal requirements for water, is putting the Everglades back on track. The knowledge base for this movement is summarized in this article.

The Wetland System of Hawai'i (Browning et al., 2020)

This article represents a status assessment of the Hawaiian archipelagos wetlands including the current status, stressors, and future viability. Wetlands in the Hawaiian archipelago encompass all fresh and saline lentic (standing or still water) ecotypes occurring from sea level to upper elevations. Wetlands can be separated into two categories: wetlands (bogs, upland marshes and swamps; lowland freshwater and saline marshes, and estuaries) and water bodies (ponds, fresh and saline lakes, anchialine pools, and artificial reservoirs). Historically, wetlands were located on all of the main Hawaiian Islands and a few of the Northwestern Hawaiian Islands (NWHI). Currently, wetlands are still found on all the main Hawaiian Islands and Midway and Laysan in the NWHI. However, the quality of many of these wetlands is now comprised of non-native vegetation, invertebrates, and fishes. In addition to naturally formed wetlands and water bodies, artificial reservoirs (i.e., wastewater treatment plants and stock ponds) are also classified as wetlands in the main Hawaiian Islands.

Our assessment of wetland viability, defined as the likelihood of persistence over the long term, is based on the concepts of representation, redundancy, and resiliency. The main stressors of wetland viability are development and altered hydrology, recreation and human access, water pollution, invasive animals and plants, sea level rise, flooding and erosions, natural disasters (i.e., hurricanes), and drought. Ongoing conservation efforts are helping to protect remnant patches of natural wetlands in the Hawaiian

archipelago. The conservation of these habitats depends largely on combined efforts of State, Federal, multiagency organizations, nonprofit organizations, and the voluntary support of private landowners. An analysis of four future scenarios identified a decline in wetlands viability in lieu of intensive management.

The Laurentian Great Lakes of North America (Collingsworth and Malloy, 2020)

The Laurentian Great Lakes of North America are a series of interconnected lakes that, collectively, comprise one of the largest freshwater ecosystems on the earth. Prior to large-scale European settlement, the largely forested watersheds of the Great Lakes Basin delivered few nutrients to the lakes and the lakes themselves maintained a trophic status that ranged from oligo- to mesotrophic conditions. The biotic community of the Great Lakes is relatively depauperate, which reflects the recent geological development of the ecosystem. Historically, there were two main biotic communities in the Great Lakes: those that occupied the biologically less-productive open waters of the upper Great Lakes, and another in nearshore areas and productive embayments.

Human activity in the Great Lakes Basin has brought with it a number of stressors, including land use changes, overfishing, altered nutrient loading, and invasive species. To help manage these stressors, the management communities of the Great Lakes, which represent two countries, eight states, two provinces, tribal governments, First Nations, and local public agencies, have developed a complex patchwork of governance in the Basin.

African Great Lakes (Ogutu-Ohwayo et al., 2020)

The African Great Lakes are ecologically and economically important. Their original biogeography was shaped by geological history but is being altered by habitat degradation, overfishing, invasive species, and climate change driven by the rapidly increasing human population. Most large near-shore species have declined or disappeared and become dominated by small pelagic fishes. Invertebrate and algal communities have changed and nutrients and pollutants increased with changes being more severe in lakes with high human population densities. These alterations are expected to continue. Countries sharing the lakes should, therefore, monitor and manage them to avoid reaching catastrophic levels.

The Biogeography of the Glacier Biome (Dial and Ditto, 2020)

If nutrients and a carbon source are available, life, as we know it, can actively reside nearly anywhere liquid water exists—even glacier ice and snow. Just as with tropical rainforests, temperate grasslands, and polar tundra, the worldwide collection of glacial ecosystems residing on permanent freshwater ice can be considered as a biological biome. In fact, all kingdoms of life have been found living on glacier surfaces, a land cover that extends over $1.6 \times 10^7 \text{ km}^2$, or 10% of the Earth's surface. The presence of these organisms living on glaciers leads to melting, and the melt-water they create is necessary for their existence, making the glacier biome important from a global warming perspective. While all of the Earth's glaciers have much microbial life in common, especially single-celled algae, the taxonomic orders of glacier-dwelling macroinvertebrates differ across continents.

Conservation and Management

Conservation Challenges to Freshwater Ecosystems (Reid et al., 2020)

Natural freshwater ecosystems represent the terrestrial phases of the global hydrological cycle and include rivers, streams, lakes, ponds, wetlands, as well as groundwaters. While freshwaters comprise only 0.01% of the water on Earth and constitute less than one-tenth of the global land surface area, they support > 10% of all recorded species including ~30% of all vertebrates. Freshwater ecosystems support the provision of numerous ecosystem services which range from natural flood management, to water supply, to health and mental being, to nurseries for important fish stocks. However, freshwater ecosystems, their biodiversity, and the services they provide are being jeopardized by a multitude of anthropogenic (human-mediated) stressors. Some of these threats are generated internally (habitat alteration, fragmentation, overexploitation) while others are external (invasive non-native species, climate change, atmospheric pollution). Fortunately, many options for freshwater ecosystem conservation exist and must be acted upon immediately.

Conservation of Temporary Wetlands (Boix et al., 2020)

Temporary wetlands are characterized by frequent drying resulting in a unique, highly specialized assemblage of often rare or specialized plant and animal species. They are found on all continents and in a variety of landscape settings. Although accurate estimates of the abundance of temporary wetlands are available in only a few countries, global estimations identify a decline in number and quality. The key environmental factors driving the structure of ecological communities in temporary wetlands are the duration, timing, frequency, and predictability of the aquatic and dry phases, which varies greatly with region and hydrogeomorphic setting.

Temporary wetlands have been historically neglected, but improved social awareness of the functions and values of, and increases in scientific interest, suggest that this is changing. They play a relevant ecological role in both global cycles (i.e., CO₂ emissions) and biodiversity (in proportion to their size, they contribute disproportionately to regional and global biodiversity).

Moreover, they provide valuable ecosystem services including wildlife habitat, nutrient flux to adjacent ecosystems, flood control, water filtration, and cultural services.

Three main current threats (i.e., inconsistent and inadequate regulatory protections; climate change; changes in land use) and three management challenges have been identified (i.e., management at both local and landscape scales; incomplete understanding of the ecosystem services provided by them; the need to enhance inventories). The most suitable approaches for conserving temporary wetlands include (1) regulations or other forms of protection; (2) sustainable management; (3) restoration and creation; and (4) collaborative conservation.

Wetlands of the Mariana Islands (Marshall et al., 2020)

This article represents an assessment of Mariana Island Wetlands that includes the current status, stressors, and future viability. Wetlands in the Mariana Islands are comprised of the following categories: estuarine wetlands, forest wetland/swamps, freshwater marshes, lakes, and artificial wetlands. Wetlands have been significantly impacted by human habitation in the islands, with many degraded, fragmented, or lost due to development, invasive species, fire, erosion, altered hydrology, agriculture, and pollution. Hydrophytic vegetation is primarily composed of species of grasses, reeds, ferns, and trees. Wetlands provide habitat for some species listed as endangered, while a couple of species reliant on wetlands have been extirpated.

Variables considered in analyzing current condition and future scenarios include stressors as well as conservation efforts. Considering the vulnerability of the wetlands and limited representation across the islands, as well as climate-related changes, it is anticipated that these habitats will continue to degrade in the absence of intensive or consistent management into the future.

Aquaculture Ponds (Boyd and Davis, 2020)

Capture fisheries production is no longer increasing, and production of fish, shrimp, and mollusks by aquaculture is necessary to meet the global demand for aquatic food animals. Aquaculture is conducted in freshwater areas, brackish water areas, and in the ocean. Most fish production from aquaculture is in freshwater areas, and freshwater fish are reared mainly in ponds. The global, freshwater pond surface area was estimated at 8.8 million ha in 2004. Since 2004, freshwater aquaculture production has doubled; but, because the intensity of production has increased, the global pond area in 2016 was estimated to only be around 11 million ha.

Nevertheless, the freshwater pond aquaculture area and volume is great enough for it to be included in the freshwater biome. The impact of aquaculture on the freshwater biome appears mostly negative, because aquaculture ponds tend to be eutrophic and of low biodiversity. Aquaculture pond effluents also are enriched in nutrients and organic matter and can cause eutrophication in receiving water bodies. As with agricultural production, which also has many negative environmental impacts, aquaculture production is necessary to supply the human population with food. Efforts to make food production more resource-use efficient and less harmful to the environment are critical to society.

Microplastics in Freshwater Environments (Rios Mendoza and Balcer, 2020)

The constantly increasing production and use of synthetic plastic materials are responsible for the global increase in plastic debris in freshwater environments. Microplastics (MPs) have been found in the water and sediments of lakes and rivers worldwide, with concentrations correlated with human population density. Wastewater treatment plants have been identified as one of the main point sources for MP release, including microbeads and clothing fibers. Synthetic polymers are identified by their chemical composition using Fourier Transform Infrared and Raman spectroscopies. In freshwaters, the primary synthetic polymers that have been detected are polyethylene, polypropylene, polyester, and polystyrene.

Field studies show that MPs are ingested by a variety of freshwater organisms, including clams, insects, and fish, but are retained at relatively low densities. Laboratory experiments document the effects that MPs can have on the metabolism, growth, survival, and reproduction of aquatic organisms, but usually at plastic particle concentrations that are orders of magnitude higher than those currently found in nature. The increased surface area of the small MP particles allows them to concentrate persistent organics pollutants from the aquatic environment. At this time there is limited information available on the concentration of toxic chemicals on freshwater MPs or the kinetics of the release of these compounds to organisms upon ingestion. Because MPs do not readily degrade, it is important for humans to reduce our reliance on plastic materials before their concentration in freshwater biomes reaches critical levels.

The Springs Ecosystem Biome, with Emphasis on Arid Regions (Stevens, 2020)

Springs ecosystems occur where groundwater reaches the Earth's surface, and are physically and biologically significant, complex, and highly socio-ecologically interactive ecosystems, particularly in arid regions. Nonetheless, springs are threatened by intensifying human appropriation, contamination of groundwater, and surface habitat destruction. This article reviews the literature and conceptual underpinnings of ecosystem ecology, springs distribution, typology, eco-evolutionary, and socio-cultural characteristics and processes in arid versus mesic/humid landscapes, and identify conceptual and data gaps.

This author estimates that the world's at least 2.3 million terrestrial springs produce at least 10.7 km³ of water/yr. Most ecohydrogeological characteristics and processes discussed apply to all terrestrial springs across latitude and elevation; however, aridland

springs differentially or more often have: (1) steeper environmental moisture and nutrient gradients between adjacent uplands; (2) distinctively different biotic assemblages; (3) higher occurrence of endemism and rare species in evolutionarily significant paleoregions; (4) interrupted, losing-stream springbrooks, disconnectivity that retards non-native species colonization; (5) lower levels of flow and increased ephemeral flow; (6) reduced resiliency and more dynamism in vegetation development following disturbance; (7) greater susceptibility to anthropogenic impacts that leads to (8) loss of springs habitat and increased probability and incidence of extinction of springs-dependent species.

These differences and greater conservation urgency elevate the need for improved stewardship of aridland springs. The study of aridland springs reveals much about the ecohydrology, distribution, ecological development and function, biogeography, ecological roles, and importance to humanity of springs everywhere, and the need and opportunities for enhanced stewardship of this highly endangered biome.

Headwater Streams (Richardson, 2020)

Headwater streams are the source streams at the initiation points of all river networks. These source streams may make up almost 80% of total stream length, but because of their small size and water volumes are extremely sensitive to the surrounding landscapes. Headwaters contribute to the characteristics of the downstream network in terms of water quality (nutrients, other solutes, and temperature), sediment transport, and organic matter supply.

These streams represent a distinct ecosystem as they support organisms that require relatively constant physical conditions, enemy-free spaces, or specific resources typical of source streams. The species found there are often unique to headwaters, and the key ecosystem functions usually differ from downstream in terms of being more dependent on organic matter sources from the surrounding terrestrial landscape, rather than in-stream primary production. Headwaters are also very sensitive to land use as they are strongly regulated by their surroundings, and often not protected.

Hawaiian Islands Streams (Valeros et al., 2020)

This document provides an overview of stream habitat in the Hawaiian archipelago and describes the ecological factors that have influenced the habitat over time and will influence it into the future. Stream habitats are found on the Northwestern Hawaiian Islands and all the main Hawaiian Islands. There is limited information about what stream habitats and their associated ecological communities looked like prior to human-contact. However, we assume that native flora and fauna were continuous, populations were larger than current populations with higher diversity and, as a result, were more resilient to stochastic events. These characteristics would have provided optimal canopy, good riparian zones, and limited erosion.

Currently, stream habitats are in decline, predominantly due to human-induced factors, such as channelization, development, recreation, and the introduction of invasive species. Despite this decline, there are federal, state, and private conservation efforts underway to purchase, protect, and manage these important stream habitats.

Streams of the Mariana Islands (Polhemus and Richardson, 2020)

This article provides a review of the flowing water, or lotic, ecosystems found in the Mariana Islands, with a particular emphasis on perennial streams. The geology, hydrology, and biota of these streams are discussed for the islands of Guam, Rota, and Saipan, the only islands in the archipelago which possess perennial stream ecosystems. Current integrity and future conservation of these ecosystems is also evaluated in the context of human-mediated stressors such as wildland fire, aquatic invasive species, and climate change. A provisional assessment is provided as to how the condition of such streams may change over time based on future climate scenarios.

Intermittent Rivers and Ephemeral Streams: A Unique Biome with Important Contributions to Biodiversity and Ecosystem Services (Vander Vorste et al., 2020)

The majority of flowing waterbodies throughout the world can be considered intermittent rivers or ephemeral streams (IRES) because at some point in time and space they stop flowing or dry. Despite their global abundance, less is known about this biome compared to perennial—permanently flowing—rivers. However, a recent surge in research has dramatically improved our understanding of how IRES function and what types of biodiversity and ecosystem services they support.

A cycle of terrestrial-aquatic habitat conditions caused by the periodic drying and rewetting creates a high temporal dynamic in the biogeochemistry, biodiversity, and ecosystem services of IRES. Vast amounts of accumulated sediment, organic matter, and organisms can be transported from IRES downstream to larger rivers or lakes, contributing to the global C cycle. The mosaic of aquatic and terrestrial habitats along IRES hosts high biodiversity including microorganisms, plants, invertebrates, reptiles, and mammals, with specialized strategies to resist to or recover from changes in habitat conditions. Although IRES provide a broad range of ecosystem services including provision of freshwater and cultural enrichment, there is a continued struggle to protect this dynamic and threatened biome.

Restoration of Riparian Habitats (Boisjolie et al., 2020)

Riparian areas are the terrestrial interface between freshwater and upland environments, encompassing important ecotones where aquatic and terrestrial biophysical processes intersect to create unique and dynamic habitats. Diverse riparian habitats support organisms adapted to variable hydrologic conditions associated with seasonal precipitation patterns and associated cycles of erosion and deposition. Riparian ecosystems encompass habitats for both aquatic and terrestrial species, making these areas biodiversity hotspots across river networks.

Riparian restoration is an effective conservation practice that can benefit terrestrial and aquatic organisms as well as promote water quality. Owing to their high conservation value, the protection and restoration of riparian areas has become a primary objective of land-management interests globally. Restoration practices include adjusting or targeting land- and water-management activities to meet conservation goals. Effective riparian restoration strategies will vary across biomes in response to distinct biophysical and social considerations at stream corridor, catchment, and regional scales.

Implications of Climate Change to Groundwater (Langridge and Fencel, 2020)

The net effect of climate change on groundwater depends not just on changing climatic conditions or the physical attributes of a region, but also on a wide range of human actions and management decisions. Researchers, managers, and policy makers involved with and responsible for groundwater stewardship are attempting to develop robust and innovative modeling tools, policies, and groundwater management strategies by building the capacity of individuals, groups, or organizations to adapt to the physical and social changes anticipated under climate change. These include the development of modeling tools, an increase in artificial recharge and recycled water, incentives to reduce demand, and the development of local drought reserves.

Glaciers and Ancient Carbon (Hågvær, 2020)

Glaciers participate in the global carbon cycle. They collect, produce, transform, store, and release carbon. A part of this carbon is ancient and is “captured” by the glacier in two ways. Firstly, a growing glacier may override an ecosystem and lock organic matter long enough to become ancient. Secondly, the surface of even remote glaciers “collect” aerosols containing ancient carbon. These aerosols are combustion products of fossil fuels such as coal, oil, or gas. Sooner or later, compounds containing ancient carbon are released from the glacier, and these compounds can be bioavailable. It has been shown that ancient carbon can be assimilated into food webs in glacier forelands, in glacial rivers, and in marine environments. Living invertebrates may achieve a radiocarbon age of several thousand years. Increased glacier melting due to climate change will increase the flow of ancient carbon to various food webs and may disturb radiocarbon dating of sediments.

Abstract

Of the many needs humans have for freshwater, water for domestic use is the most intimately understood by an individual because it is the water we use each day. Domestic use includes all the water used in and around the home including water for indoor use, such as drinking, bathing, cleaning, preparing food, and outdoor use, such as maintaining lawns, livestock, and gardens. Due to its importance, understanding where and how much water is needed for domestic use continues to be a high priority for communities around the world. This is particularly true as rapid growth is expected to push the world population to 9.7 billion people by 2050. In most cases, this urban growth will occur in cities, and therefore particular attention is paid to the challenges and opportunities for meeting domestic water demands in urban areas. This article explores the importance of freshwater for meeting domestic use purposes in an increasingly human-dominated world. Included is an overview of how water for domestic purposes is used, how use impacts the freshwater resources that support communities, and what the challenges and opportunities we as a society face are as water becomes a more precious resource.

Domestic Water Use Around the World

Globally, domestic water use makes up approximately 12% of the water used by humans (Fig. 1) (UN, 2018). While this is a relatively small amount compared to other water users (e.g. agriculture, industry), it represents a critically important portion of total water use. In 2015, this small but crucial use was $374 \text{ km}^3 \text{ y}^{-1}$, or roughly 129 L of water used per person per day (lpd) (FAO, 2019). However, the actual volume of water used around the world is highly variable. In countries such as Iceland, Australia, and the United States, per capita domestic water withdrawals are relatively high (600–700 lpd), while the mean reported water use can be much lower in other places, particularly Africa (e.g. Somalia, Rwanda, Benin) (Fig. 2). Of the nations that reported municipal water withdrawals for 2012, the 10 highest domestic water users withdrew on average 670 lpd per person, an order of magnitude more than the mean value of 17 lpd withdrawn by the 10 lowest users (FAO, 2019).

Differences in the volume of domestic water used are driven by a diversity of factors, including geography, cultural values, technological capacity, and wealth. Natural availability can play a major role in shaping local norms for domestic water use. For instance, arid locations or places with well-defined wet-dry seasonal patterns tend to foster communities that use water more conservatively. In contrast, communities in humid locations or with consistently available water sources often use water less conservatively (Padowski and Jawitz, 2012). Urbanization has also played an important role in altering the amount of water used in a home. Urban areas have higher population densities, which make it easier for water providers to set up efficient distribution networks that can be accessed by many people. Yet, while urban populations continue to grow many cities, particularly in the developed world, have seen overall total urban demands decrease over time. The underlying causes for this pattern are complex, but

Fig. 1 Total water withdrawals by sector for the year 2010. Adapted from the FAO Aquastat database: <http://www.fao.org/nr/water/aquastat/>.

are often attributable to some combination of higher costs for urban water (Dalhuisen et al., 2003), a shift towards demand management by urban water providers (Baumann et al., 1998), and the limited outdoor use by people living in apartments or buildings with little or no outside space (Polebitski and Palmer, 2010).

However, strong correlations have also been found between per capita increases in domestic water use and national gross domestic product (GDP). Greater incomes and higher standards of living create opportunities to build more elaborate houses with indoor plumbing on larger, landscaped properties, which can raise domestic water use both indoors and outdoors. Higher standards of living also mean that more food, clothing, and other goods can be purchased, which can also increase the amount of water used for food preparation, laundry, and other activities around a home (WWAP, 2015). Conversely, in places where GDP is low and communities lack access to basic water infrastructure, water use can be substantially less. When water must be collected by hand from distant sources, the volume available is limited by the amount that can be gathered each day (mostly by women and children). In places where freshwater sources are distant (>1 km) or are inconsistently available, domestic water use can drop dangerously low, leading to major health concerns (Howard and Bartram, 2003). While the amount of water considered “adequate” for healthy living varies by region and culture, general consensus suggests a basic domestic water requirement of 50 lpd (Gleick, 1996). As of 2012, 30 of the 145 countries reporting national domestic water withdrawal data fell below the 50 lpd minimum threshold (FAO, 2019). Of those 30 countries, 96% were in Africa (80%) or Asia (16%), highlighting the continued importance of domestic water access issues in developing countries.

Sources of Water for Domestic Use

The water used in a home, whether for drinking, sanitation, food preparation, or irrigation (Fig. 3), generally comes from either surface water or groundwater sources. For many people in developed countries, domestic water is collected from one or more sources, and is provided by a water utility or water provider for a fee. Water is usually distributed through a network of pipes, reservoirs, and water towers or pump stations, and often delivered with some degree of chemical treatment. In less developed countries, water may come from a communal source, such as a protected well or tap stand, which is free or accessible for a nominal fee, or may be purchased from a vendor who sells water to individual households. In locations where water distribution infrastructure is lacking, water vendors may be an option for people who can afford to pay, but those who cannot are relegated to drawing water for their domestic needs from unprotected sources that are sometimes far away.

Which source is used for domestic supply depends in part on the proximity of the source, the quality of the water, and how easy it is to access. For communities near relatively clean rivers, lakes, or streams, surface water often is the primary source. When communities are not near surface water sources, residents have two options; if local groundwater is available, this can provide a relatively inexpensive and clean supply, but if neither surface water nor groundwater sources are available, then technological solutions are necessary to transport water long distances (e.g. aqueducts, regional water transfer pipelines) or desalinate ocean water. Each type of source has different strengths and weaknesses that a community needs to consider.

Surface Water

Globally, surface water is a commonly used source of domestic water, and is also the predominant source used by cities. It is estimated that nearly 78% of urban residents (1.2 billion people) rely on surface water sources, using approximately 504 billion liters per day (McDonald et al., 2014). Surface water, because it sits on the land surface, is relatively easy to access but the volume and quality available tends to vary more dramatically in response to climatic factors (e.g., precipitation, temperature) and human activity. Given the critical and consistent need for domestic water, variability in supply can be particularly problematic (Jackson et al., 2001). Streams, rivers, or lakes that experience large fluctuations in flow or volume may not be able to ensure a consistent supply. To help manage variability, many surface water sources have been modified to provide additional storage, such as by damming rivers. Depending on the size of the dam and the geology of the area, a reservoir can hold up to several years’ worth of demand. According to the International Commission on Large Dams (ICOLD; <https://www.icold-cigb.org/>), >7600 reservoirs have

Fig. 2 Estimated national municipal per capita water withdrawals for selected countries for 2012. Data obtained from the Food and Agriculture Organization's AQUASTAT database (<http://www.fao.org/>).

Fig. 3 Different domestic water uses, including drinking (top left), bathing (top right), food preparation (bottom left) and landscape irrigation (bottom right).

been created to supply drinking water around the world since 1900. The volume each reservoir can hold varies depending on where they are and whether they serve a single purpose (e.g. domestic supply) or multiple uses (e.g., domestic supply, electricity production, agricultural irrigation, recreation). For example, the relatively small Lower Karori Dam in New Zealand holds $1 \times 10^5 \text{ m}^3$ of water while the Bratskoye Reservoir in Russia holds an impressive $1.69 \times 10^{11} \text{ m}^3$ (Lehner et al., 2011).

Groundwater

Groundwater is water that is stored below the land surface in large formations called aquifers and in other small pockets between soil particles, and accounts for nearly half of all drinking water worldwide (Smith et al., 2016). Unlike surface water sources, groundwater is found more ubiquitously across the landscape. The volume of groundwater on Earth has been estimated at an order of magnitude more than that of available surface water, and in general is a cleaner, more consistent source since it is more protected underground from evaporation and contamination. Being able to tap water in close proximity to where it is needed makes it a common source in areas that have no local surface water access. People who use groundwater for domestic purposes typically access an aquifer via a well or set of wells in a wellfield. The types of wells used to reach and withdraw water depend on the depth to water, the volume required, the local geology, and the financial and technological resources available. Shallow, hand dug wells are relatively easy and inexpensive to construct, but usually provide less water than wells that have motorized pumps to lift water to the surface. As such, deeper, larger volume wells are usually used to serve communities of people, whereas shallow, smaller volume wells may be suitable for single household use. While groundwater sources tend to be larger and less variable in response to climatic factors than surface water sources, they are susceptible to overuse and can take much longer to recover after declines or contamination. Withdrawing too much water from an aquifer can lower groundwater levels (Fig. 4), interrupt subterranean contributions to surface water sources, or lead to aquifer compaction and reduced storage. Monitoring groundwater withdrawals and aquifer response is a critical part of managing wells and wellfields for sustainable domestic use.

Other Sources

A small but important percent of the population lives in communities without adequate local surface or groundwater sources. In these communities, residents must depend on non-traditional sources to meet domestic water needs. In rural areas or communities where GDP is low, residents may pay water vendors to bring water to individual households or collect and store rainwater themselves. In urban areas or developed nations, residents may have the resources needed to invest in infrastructure or

Fig. 4 Water that infiltrates the soil and rock below ground is called groundwater. When water is pumped from wells, the water table near the well is affected (as shown above). If water is withdrawn from the well at a rate faster than it can be replenished, either by infiltration or from surface water leakage, then groundwater levels will become lower. Adapted from USGS <https://water.usgs.gov/>.

new technology to bring water from distant sources, or treat low quality water to drinking water standards. Depending on their location and finances, communities with access to ocean water or brackish groundwater may choose to use desalination technology to remove impurities and purify water up to domestic use standards. In 2016, there were over 18,000 desalination plants in operation worldwide, most of which are located in the Middle East or Northern Africa, capable of producing up to 95 million $\text{m}^3 \text{day}^{-1}$ (Voutchkov, 2018). In other cases, cities have paid to have large aqueducts or pipelines built to bring water from distant sources to their residents. The city of Los Angeles in the United States is widely known for its 674 km aqueduct system that transfers water from Owens and Mono Lake to urban residents. While not all water transfers are across such far distances, cities relying on remote sources currently move up to 83 billion liters of water per day (McDonald et al., 2014).

Clean Water for Domestic Use

Domestic use makes up a small percentage of the total water used, yet the water quality standards are among the highest of any water use sector. Clean water is paramount for protecting human health, but most surface waters experience some degree of pollution, whether in the form of particulate matter, pesticides, or excess nutrients from agricultural runoff, oils and chemicals from urban roads, or bacteria and viruses from human and animal excrement washing into water sources. Groundwater sources tend to be cleaner, as water recharging aquifers must first filter through layers of soil and sediment that remove many potential contaminants. Ensuring that drinking and domestic use sources are of sufficiently high quality is critically important for supporting optimal human and environmental health. Part of ensuring clean water is available for domestic use lies in having the ability to protect, treat, and distribute water.

Protection

Protecting water sources has become more important as urbanization and land use change has converted natural areas, which previously helped purify water, into farmland, human settlements, or industrial sites. Protecting sources safeguards groundwater and surface water from contaminants and helps keep treatment costs down. As such, water managers have gone to great lengths in some areas to ensure water supplies come from pristine, protected environments. Some places, like the cities of Seattle, Portland, and New York City in the United States, have spent decades protecting and grooming large portions of their source watersheds, shielding them from development and human activity. Consequently, these systems produce high quality water that requires little to no filtering before use. Groundwater protection is also important, especially in rural areas where septic tanks and agricultural runoff may be able to infiltrate into drinking water aquifers, and in developing countries where bacteria from open defecation can run into poorly protected wells (Ivey et al., 2004; WWAP, 2017). Strategies for protecting the area around groundwater wells vary by location and community, but include actions such as establishing an off-limits buffer area around wellheads, adding above or below ground remediation filters to remove pollutants before they reach a well, and encouraging a change in land use or best management practices for land owners near the wellheads.

Treatment

When protection alone is inadequate, domestic water can be treated before use. Water treatment is common throughout the developed world, and comes in a variety of forms, ranging from filtration and reverse osmosis to chlorination, ozonation, and ultra violet disinfection. The type of treatment needed depends on the contaminants present, which can be metals, minerals, sediment, organic and inorganic compounds, and/or bacteria. The scale of treatment ranges from individual treatment systems that can be installed for a single private well or household, up to large water treatment facilities that process water for millions of people at a time. The cost of treating water varies depending on the volume of water that needs to be treated and the amount and type of pollutants that need to be removed. Globally, 9 in 10 large cities relying on surface water sources have seen their source watersheds lose significant areas of forested or natural land to development, leading to higher drinking water treatment costs for billions of people (McDonald et al., 2016). In places where treatment isn't available, waterborne diseases (e.g., parasites such as *Giardia*, *Cryptosporidium* or bacterial infections leading to typhoid or cholera) can exact heavy tolls on human health (Moe and Rheingans, 2006).

Delivery

Protecting sources and treating water are both important elements in providing safe water for domestic use. A final layer of protection comes from the protection afforded during delivery. The concept of protected delivery dates back centuries; water was delivered via Roman aqueducts to preserve water quality as it passed through human settlements, and qanats provided a protected subterranean water delivery system to ancient communities that currently would have been located in present day Syria (Lightfoot, 1996). Today, the type of delivery infrastructure relied upon by water users typically comes in the form of piped networks or vendors who deliver water, but making sure those pipes or vessels carrying the water are clean is critically important. Broken pipes, or parts of a distribution network that are compromised, can provide an opportunity for bacteria, sediment, and other pollutants to enter the delivery system with serious health consequences. For instance, in the city of Flint, Michigan in the United States, treatment by-products reacted with pipe materials to cause severe water pollution and illness in end users (Hanna-Attisha et al., 2015). However, when working properly, a piped water network distributes treated water from a centralized facility throughout a community, maintaining high water quality throughout the delivery process.

Challenges to Domestic Water Provision

Despite the major strides society has made in developing infrastructure and technology to improve water availability and quality, not all people have access to a safe domestic water supply. Estimates vary, but it is believed that 2–4 billion people live in areas with either a geographic (e.g., physical) or temporal (e.g., seasonal) mismatch between how and when water is needed and when it is available (Mekonnen and Hoekstra, 2016). Another 1.6 billion people live in places where water could be available, but isn't due to a lack of necessary infrastructure or technology (UN, 2018). Finally, there are many regions where water is still accessible and available, but supplies are being used at a faster rate than they can be replenished (Boithias et al., 2014). Each of these cases presents a critical challenge for communities, as it impacts not only the economic prosperity and health of the residents, but also has detrimental impacts on the environment which can hamper key ecosystem functions and services (e.g., soil retention, vegetative-induced cooling) that humans rely on.

Environmental Impacts

A major consequence of appropriating water for human use has been the changes in the timing and amount of water available for maintaining riparian and aquatic ecosystems (Mekonnen and Hoekstra, 2016). These changes bring a range of impacts for freshwater ecosystems, degrading breeding habitats of water-dependent species, altering water temperature, changing flow patterns, and impacting water quality. When water is scarce, rivers, lakes, and aquifers have often been drained for human needs or have become too polluted to use. Most river systems need to retain anywhere from 20% to 50% of their annual flow to maintain reasonably healthy freshwater-dependent ecosystems. Yet many basins in Asia and North Africa, and several basins in Australia, North America and Europe are currently withdrawing water at rates exceeding these levels, pushing their basins into high environmental water stress (Smakhtin et al., 2004). This stress is complicated by the fact that while dams and reservoirs have revolutionized water management around the world and made water more consistently available to millions of people, they have also had profound effects on local and regional hydrology and negative consequences for plant and animal species that depend on free-flowing rivers to survive. Concurrently, in locations where groundwater use is intensive, coastal aquifers are experiencing saltwater intrusion, while other groundwater sources see water levels drop, leading to land subsidence and aquifer compaction. Mexico City is a cautionary tale to other groundwater users, having experienced an 80 m decline in groundwater levels and a drop in land elevation of 30 m as large withdrawals have emptied aquifers (Werner et al., 2013). Despite the fact that over half of the world's population relies on groundwater, a third of the world's biggest groundwater systems are already in distress (Richey et al., 2015).

Health Impacts

Identifying and helping communities that lack safe drinking water and basic sanitation is one of the United Nation's Millennium Development Goals (WHO/UNICEF, 2017), which target over 2 billion people, mostly in Sub-Saharan Africa and Asia, who are still in need of assistance (Fig. 5). The WHO/UNICEF Joint Monitoring Programme for Water Supply, Sanitation, and Hygiene (JMP) assists in this goal by monitoring national, regional, and global efforts to develop safe and accessible drinking water and sanitation services (<https://washdata.org/>). Currently, the JMP estimates that only 89% of the global population has access to safe and affordable drinking water (UN, 2018); in the form of a nearby, improved water source that is free from contamination. Improved water sources can include boreholes or tubewells, protected dug wells, protected springs or rainwater collection vessels, or public taps or standpipes (WHO/UNICEF, 2017). These safe drinking water sources are easier to provide to urban residents, where high population density and relative economic prosperity allows governments to more easily establish and provide water services to residents. As a result, only two out of five people in rural areas use piped water supplies, whereas four out of five people in urban areas have access to piped water (WHO/UNICEF, 2017). Yet despite the progress made in urban communities, reports indicate that cities are increasingly finding difficult to keep pace with resident's water needs, particularly in the developing world (WWAP, 2015; WHO/UNICEF, 2017). Unplanned, rapid growth can contribute to increased eutrophication and bacterial contamination of local water sources. If these sources are the supplies for the urban community, their contamination can cost residents large sums of

Fig. 5 Drinking water access by region. Safely managed sources are those from improved water sources located on premises, available when needed and free of contamination. Basic service is water from an improved source that takes <30 min to collect. Limited service is water from an improved source that takes >30 min to collect. Unimproved are sources obtained from an unprotected dug well or unprotected spring. Surface water is water drawn directly from a river, dam, lake, pond, stream or canal. Data compiled from JMP database: <https://washdata.org/data>.

money to treat, or force residents to develop a new source of water. The JMP estimates that to keep pace with current water supply and sanitation services at a 2015 standard, 700 million more people would need to be granted access to safe water (WHO/UNICEF, 2006). Yet, despite best efforts by global agencies, non-profits and local governments, water pollution and a lack of access persist.

Increased Competition

The mounting pressures society faces from rapid population growth are acutely expressed in how water is managed for human and environmental benefit. As populations grow, more water is needed not only for domestic uses, but for energy production, growing and processing food, and supporting more manufacturing and industry development. Yet the water resources available for these needs are finite and shrink as water is increasingly parsed across these sectors. As the volume of water available to meet these needs decreases, there is little buffer left to absorb instances where peak water needs co-occur across different water user sectors (Khan and Hanjra, 2009). As such, communities and water managers are more frequently seeing water needs fail to be met. This often happens in summer months, when indoor and outdoor water use is highest, farms are irrigating crops, and the water cooling systems at power plants are at full capacity as energy demands spike (Barnett et al., 2005). In places where this increased competition for water has already started, dramatic declines have been observed in the quality and health of environmental systems, which are usually the last to be considered when competing against uses that directly support human needs.

Climate Change

Water scarcity issues are further compounded by the growing impacts of climate change. Rising temperatures are creating new weather and atmospheric patterns that are altering water supply availability. These changes make it more difficult to predict the volume and distribution of rain and snow, and consequently how much water will be in rivers or will recharge to groundwater sources. While modeling efforts to understand this new “norm” are ongoing (Haddeland et al., 2014; Gosling and Arnell, 2016), water managers must rely on changing and incomplete information to make long-term decisions about how to meet growing demands for water while coping with current issues of acute water stress. The limited information available to decision-makers means that policies and strategies adopted for securing and maintaining existing water sources may not be sufficient for future needs, and the complexity of understanding the full range of biophysical, economic, and social impacts further complicates matters (Navarro-Ortega et al., 2015). By 2050, computer models suggest that the combined pressures of population growth and climate change will increase the number of people without regular access to water to >2 billion (Vörösmarty et al., 2000), and another 4.8–5.7 billion (64–76% of the global population) will face water scarcity at least one month per year (WWAP, 2018).

Future Opportunities

Freshwater systems are under acute strain from human use, including domestic water use. Where and why these systems are under pressure varies depending on a complex array of social, economic, and environmental factors. However, a water scarce future is not a predetermined fate. Recent estimates suggest that, while the number of people on the planet has increased dramatically, total water use per person is projected to decrease from a mean volume of 640 m³y⁻¹ to 580 m³y⁻¹ by 2025 due to water use efficiencies (Vörösmarty et al., 2000). In fact, water users have become increasingly aware of water scarcity issues and are collectively taking action to address the human and environmental impacts of increasing water demands. The actions being taken are range from individual to regional; from management and policy changes to implementation of new technology.

Improved Prediction

From a scientific and management perspective, one major advancement towards reducing water scarcity is being able to identify where and why it is occurring. Managers, scientists, and engineers are working together to better monitor, model, and predict how water availability and quality are changing at the local, regional, national, and global scale. Cheaper, smaller, and easier to deploy sensors are giving scientists and managers more precise and real-time information about how water resources used for household purposes are changing with time. These data in turn support increasingly sophisticated models that can more accurately assess how climatic, biochemical, economic, and policy changes alter current and future water availability and quality under a variety of possible future scenarios. This is particularly important in the face of climate change, where historically effective management strategies may no longer be economically or environmentally viable.

Water Conservation

From a community perspective, one of the most obvious pathways for addressing water scarcity issues worldwide is water conservation. Historically, community water providers would multiply expected population growth by current per capita domestic water demand to predict future water needs. If existing sources were not projected to be able to meet this future need, new sources of water were developed. Today, more water providers in developed countries are monitoring water use, and reporting a stabilization or reduction in total water demand, even as population increases (e.g., Rogers, 1993; Renwick and Green, 2000; Olmstead and

Stavins, 2009). This is due in part to the urbanization process, but is also due to water provider's increased focus on demand management through concerted customer education campaigns on how to reduce water use at home. In the US, Europe, and Australia many water providers offer rebates to replace old water-using appliances with newer models that use less water, and provide financial incentives to households to replace water-intensive landscaping with plants and features that require less water. As water conservation becomes ingrained in society, water demands are expected to continue to stabilize or decrease.

Technological Advancements

New technology is also relieving water scarcity issues. While desalination technology is not new, updated techniques and equipment have made the desalination process more efficient and less costly. Similar technology has allowed water recycling or water reuse to become more readily incorporated into water providers' portfolios of supply options (NRC, 2012). Recycled water is either filtered or decontaminated using processes similar to those used to desalinate water. While recycled water is still not widely used in the domestic sector one exception is in Singapore, where NEWater facilities use membrane technology to treat low quality water to drinking water standards. As of 2016, Singapore has five functional NEWater plants that are supplying 40% of the nation's domestic water needs (Lee and Tan, 2016). In the developing world, new technology is also being used to bring clean water to communities in need. Non-profit organizations like Engineers Without Borders (<https://www.ewb-use.org>) help low-income communities evaluate their water needs and options, and help communities construct solar pumps, boreholes, and simple filtration systems to access previously inaccessible sources.

Conjunctive Water Management

Thinking more strategically about where domestic use is overtaking source water supplies has become a critical preoccupation for water managers, particularly in the face of climate change and an increased uncertainty in the timing and availability of water. As such, some water providers are diversifying their source water portfolios, relying on not just a single sources, such as a reservoir, but rather a combination of water from different sources (Danilenko et al., 2010). Sometimes referred to as "conjunctive use", this strategy typically relies on a combination of surface and groundwater supplies, where one acts as a primary source, and the other can be tapped in times of high demand or when the primary source becomes overly stressed. However, conjunctive use can also refer not only to having the ability to access multiple different sources, but being able to move water between them. The concept of using groundwater as a refillable reservoir has been considered for decades, and some places have developed strategies for safely pumping surface water or highly treated wastewater into an aquifer as a means of enhancing or augmenting that groundwater source (Dillon, 2005).

Green Infrastructure

Finally, communities are also rediscovering the compounded benefits of creating spaces that work with the environment to provide critical ecosystem services. There has been a resurgence of interest in the idea of incorporating "green" infrastructure into towns and cities (Sandström, 2002; Benedict et al., 2012). Green infrastructure refers to soil and plant based structures that are able to capture, retain, remediate, and slowly release water that might otherwise have passed rapidly through an area (e.g., in periods of heavy rainfall, or runoff from paved surfaces). These structures can be large or small, ranging from backyard rain gardens that are designed to trap local runoff during rain events, up to large stormwater retention ponds that can hold thousands of liters of water. While often green stormwater infrastructure is not a direct solution to domestic water scarcity, it does provide a return to a more "natural" hydrologic state in places that have been developed by humans. In doing so, residents gain improvements in soil water retention and water purification, receive additional flood benefits from structures that trap water from rain events, and these natural structures often act as small wildlife refuges that bring birds, pollinators, and other beneficial species back into the area (Connop et al., 2016).

Drinking water is a critical and vital resource that warrants concerted attention to ensure that our water sources remain available and clean for generations after us. Ensuring that our water use habits are both equitable and environmentally friendly still remains a major challenge. While rapid population growth and urbanization have led to substantial declines in water availability and quality in many regions of the world, a greater societal awareness of this trend is inspiring new ideas, inventions, and attitudes towards water as a resource.

Abstract

The use of freshwater in irrigation arose in the world's first civilizations and remains critical to the planet's food supply today. This article first provides some historical context for irrigation before tackling the question of competing demands for water, discussing how coordination among irrigators is achieved and the complex relationship between irrigation and water conservation and reuse. The discussion focuses on four countries—the United States, India, China, and Chile—which provide insight into the importance of irrigation, as well as current challenges.

Introduction

Around 12,000 years ago, towards the end of the last ice age, the climate warmed and the first agricultural revolution began. In Egypt and Mesopotamia, access to low, flat floodplains provided moist, fertile soil ideal for cultivating cereals. Flood and drought, however, created huge variability in agricultural output, and the wealth of the societies themselves. Ever since, harnessing rivers, and much later aquifers, to provide water during shortage and store water during abundance has been one of the key challenges of civilization.

The amount of water needed to successfully grow crops varies, but staple cereals typically require somewhere between 450 and 700 mm per year. Fig. 1 shows that a good portion of the earth's land area is below this amount of precipitation, suggesting that the use of supplemental irrigation water is critical for food production in areas of every habitable continent. Through time, irrigation techniques and infrastructure have advanced, harnessing and moving huge volumes of water in the world's arid regions.

Yet key challenges remain. The intensification of water use has also increased water scarcity. Climate change will place pressure on the world's water infrastructure, and population growth in arid regions will strain water allocation institutions. If current trends continue, by 2025 up to a third of world's population will be living in regions where water withdrawals exceed 60% of the amount available, water primarily used for irrigation (Grafton et al., 2011). The increasing intensification of withdrawals will have profound effects on the water resources themselves, reducing flows for ecosystems and the services they provide. This article first provides some historical context for irrigation before tackling the question of competing demands for water, and key challenges in managing freshwater for irrigation across the globe.

A Brief History of Irrigation

The earliest archeological evidence of irrigation is dated circa 6000 BCE in the Jordan Valley. In the subsequent millennia, irrigation spread throughout Persia, the Middle East and westward along the Mediterranean, as well as to some parts of Asia (Bjorneberg et al., 2002). For instance, irrigation has existed in India for at least 5000 years in the form of minor irrigation works operated by households to irrigate small patches of land. Large-scale irrigation emerged much later, requiring coordination and investment that only a centralized state government could provide. For example, canals were introduced in India during medieval period (around 1220–1250).

Throughout ancient and medieval periods, irrigation has been linked to the growth and expansion of various empires (Reddy, 2017; Bjornlund and Bjornlund, 2009). In prehistoric America, the Hohokam people in the American Southwest built an estimated 850 miles of waterways in the 15th century (Nurzaman, 2017). This irrigation infrastructure supported the largest population in the

Fig. 1 Worldwide annual precipitation averages. Data from WORLDCLIMAP and ESRI.

present-day United States with 500 canals providing irrigation to around 80,000 people, the remains of which can be still found near Phoenix, Arizona (Rose, 2014).

In Europe, Spain has long history of irrigation spurred by its arid Mediterranean climate (Plusquellec, 2009). With a shortage of sites for constructing of dams, Spanish irrigation works focused on canals managed and financed by water user associations. The majority of irrigated land in Spain today is still based on the traditional systems and irrigator organizations, which have been recognized under revisions to the country's water law (Palerm-Viqueira, 2010; Plusquellec, 2009).

Where it has occurred, modernisation of irrigation took place at different times in different areas. In the American West, the late 19th century saw advanced irrigation development in California and Colorado, by Mormon settlers in present-day Utah, and Hispanic farmers in formerly Spanish areas of southern Colorado and New Mexico. Development of irrigation organizations, which started with co-ownership of irrigation networks and eventually evolved into county-sized irrigation districts, helped transform the American West into vital national and international food source (Nurzaman, 2017).

In Asia, the destruction of traditional irrigation systems and the exploitation of water and land resources during colonial rule led to delayed adoption of modern irrigation techniques. The adoption of widespread irrigation coincided with the Green Revolution in the 1960s, which also included the introduction of fertilizers, pesticides and high yield seed varieties. Combined with irrigation, these new practices led to a massive increase in food production. However, the associated ecological impacts, especially related to the ongoing decline and pollution of groundwater, remain a key challenge (Davies, 2003; Fitzgerald-Moore and Parai, n.d.).

The world's harvested land increased by about 24% from 1961 to 2003; out of which 28% was irrigated. Approximately 70% of the world's irrigated land is in Asia, where it accounts for almost 35% of cultivated land (Molden et al., 2007). Fig. 2 shows the intensity of irrigation in terms of how much of a one-kilometer grid is irrigated. That the majority of intensely irrigated land lies in India and China suggests just how critical irrigation is in feeding the world's two most populous countries. Growing reliance on irrigation led to physical changes in freshwater habitat, such as draining wetlands and building dams, and modification of water regimes through water extraction and pollution (Molden et al., 2007). In later sections we discuss the human and economic cost of India's reliance on groundwater for irrigation and China's recently completed South-to-North water transfer project.

Competing Demands

Increasing water diversions, especially for agricultural irrigation, have significantly affected the health of the world's saline lakes. Diversion in the Aral Sea watershed reduced lake area by 74% and volume by 90%, with significant environmental and economic impact. Salinity increases in the Aral Sea have led to the collapse of a commercial fishery that had once harvested 40,000 metric tons annually and provided around 60,000 jobs. Water development and river diversions by Mormon settlers, and later residents of the state of Utah, produced persistent reductions of flow into Great Salt Lake. Today, the lake's surface area is about 50% of what it was when settlers first arrived, and a 29% increase in inflows is required to restore fully-functioning ecosystems. In California, the City of Los Angeles diverted all inflow away from Owens Lake in eastern California, drying the lake and increasing air pollution.

Two approaches have been used to preserve saline lakes. First, as in the case of the Aral Sea, is the construction of a smaller lake to match the decreased flow into the lake. However, the costs of constructing the lake, together with the loss of ecosystem services and

Fig. 2 Worldwide intensity of irrigated land. Data from the Food and Agriculture Organization of the United Nations and ESRI.

the cost of mitigating the dust impact, need to be included in evaluating the trade-offs between water withdrawals and reduction of lake area. Second, as in the case of Mono Lake in California, is the litigation of minimum water delivery needed to preserve the lake. The downside of this approach is cost of the projects and the loss of water for withdrawals and use in economic production (Wurtsbaugh et al., 2017). Absent preservation, a dry lake has large economic consequences; Los Angeles has spent billions of dollars to mitigate the effects of its drying of Owens Lake.

Irrigation Institutions

Irrigation moves water from where it is abundant to where it is needed. Doing so involves solving both technical and organizational challenges. When several irrigators utilize the same infrastructure, for instance a mutual canal, the organizational form matters as much as the technology. Irrigation systems in Nepal, as discussed by Ostrom et al. (1999), provide a clear example of the issues associated with ignoring the local governance aspect of irrigation. Nepal introduced a government-owned irrigation system in 1988 to replace some farmer-owned systems (Ostrom et al., 1999). The government systems provided technical improvements over the local systems, as they had concrete and steel head works which required less maintenance and worked more efficiently than the original mud and stone head works. However, the cropping intensity achieved by the farmer-managed irrigation system, which were coupled with social norms governing the allocation of water and maintenance labor, were substantially higher than was observed on the government systems (Hilton, 1992).

In the United States, irrigation was originally undertaken by individuals and private enterprise. For-profit canal companies and dams, however, soon faced difficulties because the canal works were linked directly to a fixed group of farmers. Farmers could withhold payment and canal owners could withhold water, leaving both vulnerable. Further, operating a canal required significant organizational capacity. As a result, private canal enterprises were soon replaced by mutual ditch companies, where irrigator-owners invested time and money in the construction of a ditch for a share of water. These enterprises solved the market power problem by combining the construction and operation of the canal infrastructure with the farmers themselves. However, small groups of farmers were still unable to compel participation and payments from unwilling participants, limiting the scale of irrigation enterprises. For this reason, the irrigation district, with governmental taxing authority to raise money for infrastructure, emerged as the dominant institutional structure. These districts solved the problems with large-scale coordination by electing boards and raising revenue sufficient to contract for water deliveries to irrigate hundreds of thousands of acres (Bretsen and Hill, 2007).

Another irrigation institution found in the US West, particularly in New Mexico, is the *acequia*. In place since the southwest United States was under Spanish and Mexican control, acequias are a decentralized but complex legal institution characterized by both Spanish and Anglo-American water law (Smith, 2016). These systems were generally replaced by irrigation districts in the early 20th century in order to centralize the organization of additional irrigated acres. However, where irrigation did not expand, acequias have worked as well as irrigation districts in coordinating irrigation (Smith, 2018).

Water Conservation and Reuse

With sites for storing additional surface supply dwindling, groundwater tables declining, and demand for in-stream water for ecological purposes increasing, competition for water resources is contentious. Most human use of freshwater across the globe is for irrigation, so improved technology has the potential to conserve a large volume of water, and to do so with little or no loss in crop yields. For instance, replacing flood irrigation, where water is allowed to flow out across a field, with sprinklers can save 10–35% of the applied water (Negri and Brooks, 1990). However, realized savings depend on the attributes of the system, the physical characteristics of the field, and the rules and institutions governing water use.

Implementing sprinkler irrigation has challenges. Sprinklers tend to save labor while gravity systems have lower upfront costs (Ge et al., 2018). Traditional gravity systems applied to land with high water holding capacity can achieve application efficiencies comparable to sprinklers. Conversely, land with porous soils or steep slopes is unsuitable for gravity systems because of deep percolation or runoff. Water saving irrigation technologies also include drip irrigation, where evaporation is limited by applying water via a buried hose, and tail water recovery systems which capture irrigation water for reuse. Drip irrigation is more expensive than sprinkler systems and it is relegated to small areas, generally devoted to specialty crops. The viability of a tail water recovery system is determined by soil texture, growing season length, and soil productivity. The cost of water, including pumping costs, affects the decision to adopt a water saving technology. Generally, however, water costs are low and irrigation efficiency improvements may not appear especially responsive to water prices (Negri and Brooks, 1990).

Even where adopted, the use of efficient irrigation technology is not enough to ensure more water availability. Termed the “irrigation efficiency paradox,” increased water use efficiency can actually lead to little gain in usable water. This is both an accounting and behavioral problem. Because non-consumptive water uses at a particular farm may be recovered and reused at the basin level, measuring water use at too fine a scale can overestimate the savings of efficiency improvements. Technologies that make crop production more efficient may induce farmers to switch to water-intensive crops or even apply more water to the same crop when a marginal yield response from additional water occurs. In Idaho, USA the reduction in groundwater recharge as a result of more efficient irrigation has reduced the Eastern Snake Plain Aquifer by about 30% since the mid-1970s, despite an increase in precipitation (Grafton et al., 2018).

Countries like the United States, Chile, and Australia have utilized markets to allocate water and create incentives for conservation. Property rights to water are separated from land and are traded in a market as a separate good. In opening the option for irrigators to sell conserved water, markets create incentives for investment in conservation without subsidies. However, while effective at incentivizing conservation, allowing irrigators to sell water still requires careful planning to avoid unanticipated issues, like those associated with the irrigation efficiency paradox. Grafton et al. (2018) suggest five actions to create effective policy for water conservation:

1. Development of physical water accounts from farm scale to basin scale with details on who gets what and where.
2. Establishment of a cap on water withdrawals or irrigated area.
3. Assessment of risk using accurate measurements from on-ground monitoring of flows.
4. Requirement of a payoff from subsidizing irrigation efficiency investments that includes the costs associated with reduced return flows.
5. Monitoring of the behavior of irrigators to ensure water extractions are consistent with established rules.

United States: The Value of Irrigation

In the United States, the 98th Meridian approximates the divide between the humid east and semi-arid west. A lack of adequate water for agricultural production is one of the defining characteristics of the American West. Early in the development of its agricultural economy, the western US saw two severe, prolonged droughts that led to significant political and social change. Drought from 1890 to 1896 led to a dramatic reversal of westward immigration trends and economic depression across the Great Plains. The drought was the primary impetus for the beginning of federal involvement in irrigation, leading directly to the Reclamation Act of 1902, although with limited impact initially. The Dust Bowl, a period of drought and wind erosion that occurred in portions of the Great Plains from 1930 to 1936 is perhaps the most important human-natural disaster in American history (Hansen and Libecap, 2004; Hornbeck, 2012). Compared to these early droughts, which transformed the social and economic lives of residents of western states and altered migration patterns, later droughts, similar in magnitude, appear to have been much less impactful. As Hansen and Libecap (2004) point out, droughts in the 1950s and 1970s did not result in the same levels of wind erosion, nor similar levels of economic or social upheaval.

The likely explanation is irrigation. Irrigated acreage remained relatively stagnant in the early 20th century. Beginning with the completion of the Hoover Dam in 1936, federal reclamation projects began to deliver water across the west and increased irrigation rates in many areas. Starting in the 1940s, technological innovation allowed for widespread adoption of groundwater irrigation on the Great Plains (Hornbeck and Keskin, 2014, 2015) and across the west (Edwards and Smith, 2018). As a result, irrigated acreage doubled from around 20 million acres in 1940 to 40 million acres by 1978.

In the Great Plains today, one of the world’s largest underground freshwater resources, the Ogallala Aquifer, provides significant water for irrigation. However, prior to the mid-1940s the aquifer had no impact on agriculture as the water was too deep to be

accessed. Following World War II, new irrigation technology and the availability of energy for pumping water made Ogallala groundwater available. Rates of irrigation increased from nearly zero to almost 20% of all farmland acres by 1997, leading to an increase in land value (Hornbeck and Keskin, 2014). In the entire western United States, including the Great Plains west of the 98th Meridian, areas with large streams or groundwater as irrigation sources increased crop production by \$19 billion after 1940, around 90% of the subsequent total increase in crop value in the western US (Edwards and Smith, 2018).

Areas where irrigation is present may be better able to better deal with weather variability, maintain harvest levels, and decrease failed acreage during periods of severe drought (Hansen et al., 2011; Edwards and Smith, 2018). However, increased access to irrigation has short- and long-run impacts. In the short run, farmers increase irrigation intensity, giving rise to higher productivity and less drought-sensitive crop yields. However, in the long run, this entails a movement towards more water intensive crops, potentially increasing drought sensitivity. On the Ogallala Aquifer, irrigation withdrawals after 1940 quickly surpassed the natural recharge rate; a phenomenon observed throughout the world. While agricultural land values remained lower in nearby counties, agricultural production adapted in a way so that counties with access to groundwater are actually more sensitive to drought (Hornbeck and Keskin, 2014).

India: Groundwater and Subsidies

Groundwater is critical, and problematic, in India, where high agricultural intensity combined with poorly planned energy subsidies create incentives for unsustainable irrigation water use. According to the World Bank, groundwater irrigation contributes up to 10% of India's GDP (Shah et al., 2004). Energy subsidies were introduced by the Indian government to allow poor farmers to access to water for irrigating high yield crops in the 1970s (Shah et al., 2004). After the implementation of the subsidy, the land with available groundwater increased by over 300% due to non-existent costs of pumping (Schoengold and Zilberman, 2007). As agriculture grew, it became increasingly difficult to install, monitor, or maintain meters for pumps. Hence, flat tariffs were implemented, which do not effectively incentivize water conservation.

Today, the lack of regulations on groundwater withdrawal threaten the viability of the electrical power sector and groundwater sustainability. Yet it is the impact of these subsidies on low income and rural households that is a roadblock to removing them. Irrigation has eliminated famine in India and groundwater is the backbone of Indian agriculture, supporting 70%–80% of irrigated output.

Shah et al. (2004) suggest that surface canal systems may be a viable alternative, and could be incentivized by raising the flat rate per hectare irrigated to a level that ensures the overall viability of the system. Alternatively, Indians could look to the groundwater-energy nexus, a framework for understanding the relationship between the consumption of water and energy, for a solution. The regulation of electricity for pumping could curtail wasteful use of groundwater through a direct tariff, or through restricting the availability or the electrical supply to pumps.

China: The Impacts of Moving Water

The majority of China's freshwater resources are located in the southern part of the country, whereas the key population and agricultural production centers are in the north and east (Jiang, 2009; Magee, 2011). Increasing groundwater depletion in arid northern China, where groundwater is the main source of supply, has given rise to issues like seawater intrusion and land subsidence. The Yellow River in the north has suffered completely dry periods in 22 of the past 28 years (Magee, 2011). Conversely, the Yangtze River in the south's rising water levels have threatened the lives and property of millions of people. In 1998, flooding on the river resulted in approximately 4000 deaths (Magee, 2011). To try and address these issues, the Chinese government has developed the South-North Water Transfer Project. The project aims to use a series of inter-basin transfer canals to move up to 48 billion cubic meters of water per year from the Yangtze basin to the Yellow River (Magee, 2011).

However, there are potential issues. One significant concern is the quality of water actually arriving in the Yellow River and ultimately Beijing and surrounding areas. Much of the canal system suffers from acute agricultural and industrial pollution. Because the transfer system is so large, intermediate river systems like the Han River could experience drying and water quality issues as a result of diversions. A major concern for the Yangtze River is the excessive withdrawals causing saltwater intrusion due to diminished volumes of freshwater, an issue the Yellow River is already facing. Finally, among the environmental concerns, potential impacts could include disruption of ecosystem integrity in all the rivers included in the diversion as a result of the construction of new dams, the creation of stagnant water where moving waters have been the norm, and the transfer of biological contaminants and invasive species between basins (Magee, 2011). In addition to its environmental issues, socio-economic impacts are also problematic. The resettlement of more than 300,000 people, mostly from the area around Danjiangkou reservoir on the Han River, offers an example of the scale of these issues.

Chile: Extreme Water Scarcity

The northern regions of Chile are perhaps the driest in the world. The Antofagasta Region receives less than 5 mm of water per year, but as a result of being the world's largest copper producer, also sees high water demand. Agriculture currently accounts for around 33% of the freshwater consumption in the region while mining uses about 56%. Since 2003, mining firms have been denied the use of purchased agricultural water rights to protect water access for small and indigenous farming communities. This has resulted in mining firms procuring water from desalination, an economically and environmentally costly solution (Edwards et al., 2018). The direct benefits of the policy include cultural values associated with indigenous water use, avoided relocation costs and agricultural production. Moreover, the costs of relocating entire villages may be much higher than the lost agricultural production.

The challenge that the Chilean government faces in allocating water is unique because the value of water is so high, but as populations grow in arid regions, the issue of extreme scarcity will remain: should water remain in irrigated agriculture or move to industry and urban users who are willing to pay more for it (Edwards et al., 2018)? Firms and farmers can work together reach mutually beneficial agreements, but often this will require compensation for the reduction in water in agricultural communities (Edwards and Libecap, 2015).

Conclusion

Irrigation has reshaped agriculture and societies in the arid regions of the world. However, growing demand and climate change pose a threat to the sustainability of world's freshwater resources. Addressing the competing demands for water is perhaps even more critical in the developing world, where governmental institutions may be weak. Lessons can be learned from the successes and failures of irrigation development in the United States, China, Chile, and India, where irrigation intensification has led to tremendous benefits, as well as costs. Because so much of the world's water is used in irrigation, the agricultural sector is key in balancing water use in cities, ecosystems, and food production systems. Allocating water across multiple valuable sectors is the key water management challenge of the 21st Century.

Abstract

Of the fresh water (blue footprint water) from rivers, lakes and groundwater 33–88%, is directed towards agriculture in varying proportions depending on the area. Only 0.6% is used for direct consumption by livestock or indirect activities associated with livestock. The distribution of livestock on the globe is dependent on existing water and the ability of animals to tolerate water deficiency and quality. In the animal body, water has multiple functions: metabolic, growth, breeding, and production. Deprivation or deficiency of fresh water affect these functions, but species from arid and semiarid areas have developed adaptations to these conditions. There are large differences between water requirements, for livestock in semi-arid and arid area of extensive and pastoral system, compared to livestock in the intensive farming system.

Dependent on the farming system, the type of rainfed agriculture and the distance to water source, the watering frequency is different. Water quality in many regions is poor in terms of salinity and contamination with toxic elements. In arid and semi-arid areas, water usually has a large amount of chloride, which is why research is directed to choosing the most resistant species to low quality water and to develop farms in these areas as well.

Water, “the Sap of Life on Earth” and Its Distribution

Rich in water, the “Blue Planet,” cannot satisfy the needs of fresh water even if is covered by huge surfaces of water (71%). The seas and oceans sum up about 97% of the surface occupied by water and only 3% belong to surface fresh water and underground water. Of this 3%, 2.5% is stored in glaciers that cannot be a viable source of fresh water, and 0.397% is polluted water. The remaining only 0.003% of all surface of water can be used as fresh water with a very uneven distribution (Balon and Dehnad, 2006; Naqvi et al., 2015).

The most disadvantaged regions are arid and semi-arid which occupy 30% of the total area in the world and extends into 80 countries, where, the degree of evaporation is greater than the amount of rainfall (200–250 mm rainfall/year, 250–600 mm/year evaporation). North Africa, South Asia, the Middle East and Mediterranean countries located in the arid and semiarid areas of Southern Europe are the most affected regions (Kammoun et al., 2018).

Fresh Water and Importance for Livestock

The water crisis enters into category of top 10, global risks. Worldwide, 70% of blue water from rivers, lakes and groundwater is directed to agriculture with quite remarkable differences between Europe, where the percentage is the lowest at 33% and Africa with the highest percentage at 88% (Appuhamy et al., 2016).

Providing fresh water for livestock has overwhelming importance for maintenance of their vital functions and production that depends on a number of factors, such as: species, body weight, physiological state, diet, temperature, frequency of water provision, type of housing and environmental stress (<http://www.fao.org/>, 2018). Water is also used in indirect activities that include: cleaning of animals, shelters, facilities, washing and preparation of fodder, slaughtering, processing of animal products and skin tanning. However, water requirements to satisfy the need for drinking water but also for the other services is only 0.6% of the fresh water used in agriculture (Ran, 2010).

The management of water resources for livestock production must take into account several aspects such as: the production system applied (grain—fed or mixed crop-livestock), the intensive or extensive breeding system of various animal species, taking

into account also the social and cultural aspects of animal husbandry in different countries. Water requirements are higher in the extensive system than in the intensive (industrial) system (Schlink et al., 2011).

Distribution of Livestock Dependent on the Rainfed Agriculture System

Of the total cultivated area in the world about 80% is integrated into the rainfed agriculture system divided into: highlands, dry tropics, humid tropics, subtropics and temperate. Accordingly, the distribution of livestock is different.

In dry tropics, which includes the Sudano-Sahelian zone of Africa, and India, small ruminants, goats and sheep are predominant. The cattle are common in southern Africa and in Latin America. Latin America and Asia are part of the humid tropics type, the predominant livestock are sheep or cows depending on the financial status of farmers.

Poorer farmers have as their main concern raising sheep and goats, while wealthier farmers raise cows. In the subtropics, cows are often the dominant species, with goats in the southern Mediterranean, sheep in Australia and pigs in China. Developed countries in Western Europe, the United States and Canada, are part of the temperate type of rainfed agriculture, where the predominant livestock is represented by pigs, poultry and cows reared in the industrial system (<http://www.fao.org/>, 2011).

The arid and semi-arid areas of China, Australia, and India experience scarcity in water, but these regions are raising one third of the total number of cattle on the globe and 30% of the sheep and goat population in the world (Avendaño-Reyes, 2012; Todaro et al., 2016; Araújo et al., 2010). In Sub-Saharan Africa, cattle, sheep, and goats account for about 1.2 billion tropical livestock units (1 TLU = 250 kg body weight), after Descheemaeker et al. (2010).

Quality of Fresh Water Sources

The main source of water for humans and livestock in the arid and semi-arid coastal areas of Southern Europe, the Middle East and the North African region is underground water, with a chemical composition rich in chlorides as a result of natural processes (Kammoun et al., 2018). The various sources of surface water pollution in the Sub-Saharan Africa results in water in an unsafe water category (<https://thelastwell.org/>, 2019).

A quote from Mandakini (2015) "Water, water, everywhere, nor any drop to drink," best describes the water situation in Asia, where water is contaminated with human fecal microorganisms and, in addition, contains large amounts of arsenic especially in shallow groundwater (Luby, 2008). In Kenya, large amounts of copper and nitrate are found in fresh water (Wayua, 2017). Water rich in sulphates can be found in the semi-arid rangelands of the western region USA, Minnesota's groundwater, river waters in western Canada, and in SW China (Kun et al., 2017; Cammack et al., 2012).

The Importance of Water for the Animal Body

Water in the body participates in all metabolic processes, growth and breeding, (e.g., it provides a fluid environment for the foetus). The placenta has a significant percentage of water that plays a role in preventing abortions and avoiding other problems in the reproductive sphere (Van Emon, 2015; Salah, 2018). It plays a role in lubricating joints and organs, maintaining blood volume, osmotic balance, regulating osmotic pressure and thermoregulation. Water assists in excretion of waste products such as urea from the cells for removal via the kidneys, but also from the lungs and gut. It also induces resistance against diseases. However, it may also be a favorable environment for the transport of unwanted elements, such as providing a growth medium for microorganisms. Limiting the intake of water results in reducing the amount of ingested feed with negative effects on productive and reproductive, because of retardation of ovarian follicular growth. Irregular water consumption affects production, reduces lactation and affect the animal's general health. For example, lack of water can affect vision and hearing (Patience, 2012; Grönvall, 2015; Chedid et al., 2014). Deprivation of fodder for a long period of time has as a consequence the loss of fat resources and almost all glycogen, half body protein and 40% of body weight. Compared to deprivation with feed, deprivation of water entails more serious repercussions. Loss of only 10% of body water can cause serious disorders, affect the production of milk, meat and eggs (Kubkomawa et al., 2015). However, sheep (Merino) in semi-arid or arid regions are adapted to losing about 5–7%/day of body weight daily and cows (Shorthorn) about 7–10% without being affected in any way at 40 °C, air temperature (Naqvi et al., 2015).

Livestock in semi-arid and arid areas have developed the ability to adapt to these harsh conditions through, the ability to carry water reserves in the rumen and extracellular fluid space; to adjust the amount of electrolytes in several fluid locations. Kidneys have the ability to conserve water and circulation does not have to suffer by reducing plasma volume; also, panting and sweating are lower (Constable et al., 2016).

Animal survival time with a lack of water is a few days dependent on climate and breed. Desert bighorn sheep can withstand water deprivation for 15 days, Australian Merino sheep survived for 10 days without water, while the Barki sheep in Egypt cannot survive water deprivation over a 3-day period (Naqvi et al., 2015).

Watering and Water Needs for Livestock in Different Regions

In intensive farming systems, ensuring access to water ad libitum is compulsory, as is providing the necessary water for cleaning. In low water areas, farmers administer water to cows, if not ad libitum, at least three times a day in semi-arid areas and two times a day in arid (Dhami et al., 2018).

In dry climate or drought seasons in south-central New Mexico, beef cattle on the pasture consume about 57 L/day⁻¹ fresh water. Through a single watering, they can provide 94% of their daily water consumption (Rouda et al., 1994). Black Bedouin goats, adapted to the conditions of the arid desert of Sinai, can consume the equivalent water of 45% of their body weight without haemolysis of the red blood cells (McGregor, 2004).

The amount of drinking water for livestock in Sub-Saharan Africa is estimated at 20–50 L⁻¹/day/tropical livestock unit TLU (1 TLU = 250 kg body weight (Descheemaeker et al., 2010). Cows kept in intensive systems benefit from access to water <15 m from food sources, while in arid and semi-arid areas, species of Sahelian livestock move long distances for watering without being affected the state of animal health: 6–10 km for cattle and 3–5 km for goats (Niyonzima et al., 2013). During the dry season in Kenya, livestock travel long distances even as much as 40 km, water sources (Kivunzya et al., 2018). Watering for cows in pastures in this area occurs every 3–4 days and 5–6 days for goats, which are more tolerant (Tolera and Abebe, 2007). Water consumption for a few days (4) does not negatively influence feed consumption or milk production (Naqvi et al., 2015). In contrast, high-productivity breeds will have the same requirements of the amount of water, similar to breeds grown in the intensive system, as can be seen from Table 1.

Factors That Influence Drinking Water Consumption

Factors that influence drinking water include: species, age, body condition, growing, pregnancy, lactation, fattening, individual behavior, injury and illness; or the environment: dry matter content, environmental conditions, water system and watering (discretionary or fractional), water quality, stress (Williams et al., 2016; Van Der Klis and De Lange, 2013).

Animals within the same genus may require different amounts of water. For example, *Bos indicus* cattle in northern Australia consume less water than *Bos taurus* breeds (Davis and Watts, 2016).

Feed content in dry matter affects the ingested water requirement. Animals that consume grass will drink less water because the grass has 80–85% water. Instead, grains and hay raise requirements for water consumption due to their low water content (i.e., 10–12%) (Spencer et al., 2017).

Table 1 Water intake and cleaning water requirement L day⁻¹.

Species	Water intake	Cleaning water	Species	Water intake L day ⁻¹	Wash water (L day ⁻¹)
Cattle	L day ⁻¹	requirement (L day ⁻¹)	Pigs		
Dairy cow	40–50	13–45	Dry sow	5–9	0.09
Bull	45–55		Lactating sow	18–23	Farrowing sows —5.63
Dairy cow	5/L milk		Boar	9	0.09
Yearling	25–40		Baconer	5–9	Growers (50 kg)—0.371
Calf	15–25		Piglet	4–5	Weaners (20 kg)—0.286
			(4–5 weeks)		
Sheep	Water intake L day ⁻¹		Poultry	Water requirement	Wash water (L m ⁻² floor
				(L day ⁻¹)	area)
Dry ewe	8		Laying hen cage	0.20	6
Ewe with	11		Laying hen non	0.22	6
lamb			cage		
Ram	11		Broilers	0.19	5
Lamb	2–4		Pullets	0.09	5.00
					12
Species, physiological stage, production			Water intake, depending on air temperature 15–35 °C (L day ⁻¹)		
African pastoral system-lactating 2 L milk/day			21–28.7		
Large beerd, dry cow 279 day pregnancy			44–102		
Large beerd, lactating 35 L/day			102.8–126.8		
Goat—lactating 0.2 L/day			7.6–11.9		
Sheep lactating 0.4 L/day			8.7–20.1		
Chicken, adult broilers/100 birds			17.7–62		
Laying eggs/100 birds			13.2–50.5		
Swine, lactating daily weight gain of pigs, 200 g			17.2–46.7		

From Brown, L. (2006). Livestock watering requirements, quantity and quality. Order No. 590.301.1, <https://www2.gov.bc.ca/assets/gov/>, Naqvi, S.M.K, Kumar, D., Kalyan, D., Veerasamy, S. (2015). Climate change and water availability for livestock: Impact on both quality and quantity in: climate change impact on livestock: Adaptation and mitigation, pp. 81–94, Springer India, New Delhi, India, and <http://randd.defra.gov.uk/>.

A high level of protein or salt in food rations increases the consumption of water in order to eliminate more urine required for the excretion of urea and salt. In poultry, higher water consumption is also observed in the case of rations with high content of fat or potassium (McKernan, 2012; Greg Lardy et al., 2008).

Water quality affects water consumption. For livestock, water with 1000–3000 mg TSD/L is considered satisfactory but, it can affect the faecal quality of poultry. Livestock can exhibit digestive disorders manifested by diarrhea if they are not accustomed with this kind of water (Ward, 2019).

High levels of sulphates affect the taste of water and high levels in cattle, sheep, and goats can lead to polio (Van Emon, 2015; El Mahdy et al., 2016). High amounts of magnesium sulphate can cause a drop in faecal quality in birds (Putnat, 2016). For nursery pigs, 2000–3000 ppm can cause a decrease in growth performance and increase fecal score (Flohr et al., 2014).

The most tolerant livestock to acid or alkaline water are laying hens and chickens. The maximum productive performances in broilers was recorded at pH 7.5, while, alkaline water had the most negative impact on performance (Khan et al., 2013). Treatments for pigs through the watering system may be ineffective at pH <5; 15 drugs precipitate below these values (Nyachoti and Kiarie, 2010). Large and small ruminants need to have water with a pH between 6.5 and 8.5 (Curran, 2014).

Fresh Water Requirements Depending on Physiological Stage

The state of gestation influences water consumption by increasing the amount of ingested water. In the last 4 months of gestation, dairy cows have 30–50% higher requirements for water consumption. Goats, during the advanced gestation period, have similar high requirements relative to the amount of ingested water (Brown, 2006; Ehrlenbruch et al., 2010). Water intake in sheep, progressively increases from the first to the 5th month of gestation, which means a 126% higher consumption.

A lamb's weight at birth for Magra and Marwari breeds which are adapted to desert conditions, does not suffer even if mothers are watered twice a week for long periods of time (Araújo et al., 2010; Naqvi et al., 2015). The water requirements of sows in lactation are 17–25 L⁻¹ of water per day (King, 2016).

Fresh Water Requirements for Livestock Production

A cow should normally drink about 7–10% of her weight a day. Water intake is influenced by many factors, including the type of production (e.g., milk, meat). A lactating beef cow will drink on average 95.92–56 L⁻¹/day (Lewandowski, 2015). The water requirements of most (80–90%) dairy cows are satisfied in by direct water intake. There is a linear relationship between the quantity of milk produced and the water requirements. In addition to the necessary water consumption to maintain vital functions, it is necessary to provide water to support milk production. Compared to non-lactating cows, those in lactation require a 25% higher water consumption and since the milk is 87% water it is necessary that, for each liter of milk produced, an intake of 2.5 L⁻¹ of water is required (Schroeder, 2015; Spencer et al., 2017). In dry tropics, the amount of water required for dairy cows is calculated taking into account that 1 L⁻¹ of water/10 kg of live weight, is added to the water requirement for milk production (i.e., 1.5 L⁻¹/L of milk produced) (Ibrahim, 2015).

Depending on the production system and the efficiency of red meat production, the amount of water required to produce 1 kg red meat is 180–540 L⁻¹/kg or 80 L⁻¹/kg—320 L⁻¹ in Southern Australia (Scholtz et al., 2013; Nason, 2018).

Water Consumption and Air Temperature

There is a direct proportional relationship between water consumption and air temperature. Increases in air temperature, result in increases in water consumption. In this regard, in cattle, for each additional degree higher than 40° F, water intake increases by 0.65 L⁻¹/day in dairy cows, 0.21 L⁻¹ in growing dairy bulls and 0.22 L⁻¹/day in feedlot cattle (Spencer et al., 2017).

The lactation period plays an important role in water consumption, cows at the middle and end of lactation being more susceptible to heat stress (Könyve et al., 2017). In warmer environments, the amount of water required is multiplied by 1.5 for gestating cows, and for those with calves the water intake increases by 0.87 L⁻¹ water/L milk (<http://www.fao.org/>).

After Brown (2006), the water requirement for a cow dependent on air temperature, below 15 °C or above 25 °C, varies between 4 L⁻¹ and 8 L⁻¹/45 kg animal weight.

Sows and finishing pigs are extremely sensitive to rising temperatures, which have, as a consequence, higher water consumption (Guthrie, 2011). In hot weather, rising temperatures change the patterns of drinking water of pigs, but also, the amount of water consumed, which will be 2–2.5 and even 4 times higher (King, 2016). For each additional degree of temperature compared to the comfort temperature, the water requirement rises by 0.1 L⁻¹/head/day (Schiavon and Emmans, 2000). In semi-arid and arid regions, drinking water required for the needs of animal is 4 L⁻¹/kg dry feed intake and increases by 50% in hot weather (Scholtz et al., 2013).

Bird water consumption expressed as: L⁻¹/bird/day can be an indicator of welfare and stress conditions to which birds are subjected. In addition, changes in daily water consumption may indicate health problems like enteritis and coccidiosis. It can also be a potential tool which indicates increased cases of foot pad dermatitis and deterioration of air quality due to wet litter (Manning

et al., 2007). The water consumption of broiler increases proportionally with raising the temperature. For each degree, above 20–32 °C, consumption is 6% higher. Parallel to the increase in water consumption, feed consumption decreases by 1.23% for each additional degree above the value of 20 °C (Williams et al., 2013).

Aspects Related With Water Quality

Due to either scarcity of water or poor water quality, especially in terms of the amount of total dissolved solids (TDS) or sodium chloride in different regions of the world, such as: Brazilian semi-arid region, Southern Tunisia and other regions, researches was undertaken to identify the most resistant species to these conditions, to the development of farms in these regions.

In a comparative study, Holstein cows in the semi-arid area of northern Mexico demonstrated that productive performances in cows were higher with lower feed consumption when they received water desalinated, by reverse osmosis compared with cows who received drinking water with $>1809 \text{ mg L}^{-1}$ TDS. In addition, the number of somatic cells and the percentage of cows with fat depression was lower with desalinization of water (García-Muñoz et al., 2015).

Crossbred goats from the Brazilian semi-arid region who received drinking water from the 30th day of lactation with TDS of 8326 mg L^{-1} did not show an affect in nutrient intake, digestibility or milk yield. Only water intake increases with increasing values for this parameter (Paiva et al., 2017).

In sheep, drinking water containing 1% NaCl does not affect feed consumption or growth performance of animals. In contrast, water with 1.5–2% NaCl negatively influences both; feed intake and weight gain. At concentrations above 2% NaCl, occasionally diarrhea occurred and sheep appeared is emaciated (Araújo et al., 2010). Barbarine sheep (Tunisia) who consumed drinking water with 11–15 g NaCl did show impeded growth, but, higher values (15 g NaCl), increased the creatinine and urea levels in the blood plasma, which suggested altered kidney function (Yousfi and Salem, 2017).

The milk yield of sheep who received drinking water with 10 g of NaCl over a period of 120 days was not significantly affected, but, there was a significant increase in salinity, conductivity and pH (ElGharbi et al., 2015).

Nguni goats grown in Southern Africa tolerated saline water with 5.477 g NaCl (Mdletshe et al., 2017). Adaptation of Boer Goats from the same area to water consumption with gradual increases in NaCl concentration to 1.5% NaCl led to conclusion that this method was effective to accustom the animals to the salinity of water (Runa et al., 2019).

Experimentally, it has been demonstrated that water intake with a progressive increase in the amount of NaCl up to 10‰, positively influenced the amount of ingested water in four castrated adult male goats from 2.0 to $3.2 \text{ L}^{-1}/\text{day}$, but decreased at the concentration of 20‰ NaCl. Increasing the salinity of water affects the concentration of sodium, glucose, urea, protein, osmolarity and creatinine in the blood plasma. However, potassium and body weight remained unaffected. So goats can survive with saline water for at least 2 weeks without negative repercussions (Zoidis and Hadjigeorgiou, 2017).

In desert areas, water containing 10 g sodium chloride, 20 g sulphates are considered safe for Marwari sheep and Parbatsar goats (Patil et al., 2012).

Conclusion

Water, with its multiple functions, maintains the body's homeostasis, and livestock, regardless of region, rich or poor in water, need fresh water for survival, production, breeding, even if the quantity, frequency of watering or water quality is not always the best.

Abstract

Inland fish farming contributes to the nutrition and livelihoods of many millions of people. Most fish are grown in constructed ponds or floating cages in natural or man-made water bodies. Freshwater fish farming is often integrated with the farming of crops, where wastes and by-products from one component are used as inputs for another. Developing technologies offer new opportunities to conserve water and increase the productivity of freshwater aquaculture. Recirculating aquaculture systems (RAS) have been developed with the potential to greatly reduce the water requirements and environmental impacts of fish farms. Biofloc technologies (BT) utilize in situ bacterial processes to maintain water quality and provide food for filter-feeding species of fish and crustaceans. Full integration of fish and vegetable production can be achieved through aquaponics, which combines aquaculture and hydroponic plant production within a recycled water system. This chapter reviews current developments in water recirculation techniques, biofloc technology and aquaponics against the background of increasing food security needs and water resource issues.

Challenges

Global population growth presents a major challenge in the provision of future food security. It has been predicted that by 2050 some 50% more food will be needed to feed a population exceeding 9 billion (Godfray et al., 2010). This will necessitate intensification of food production, more sustainable practices and more efficient use and protection of water and natural resources. Capture fisheries and aquaculture make a substantial contribution to global food security. Capture fisheries are fully exploited and

future increase in fish supplies will come from the expansion of aquaculture. Whilst the annual rate of increase in aquaculture production has declined from its peak in the 1980s it is predicted that aquaculture will continue to expand and by 2030 will contribute an annual 93 million tonnes of seafood to the global food supply (World Bank, 2013) (Table 1). Global food fish consumption per capita has grown from 9.0 kg in 1961 to 20.5 kg in 2017. This is an annual rate of increase of 1.5% (FAO, 2018). Fish currently represents 6.5% of all protein for human consumption where it represents a vital source of high quality protein and essential micronutrients, including various vitamins, minerals and polyunsaturated omega-3 fatty acids.

Freshwater Fish Farming

Inland fish farming is the major sector of global aquaculture producing 64% of the total global farmed fish in 2016. It has its origins in China and is most developed in China, South East Asia and Southern Asia. Diverse types of fish are produced with major emphasis on various species of carp and tilapia (Table 2; Picture 2). Freshwater crustaceans, including shrimp, crayfish and crabs are also produced in smaller quantities in inland waters.

Culture Methods

The majority of freshwater fish are farmed in extensive and semi-intensive pond systems and floating cages (Picture 1). Individual earth ponds are generally shallow (<1 m deep) and range in surface area from a few square meters to several hectares.

Extensive culture

In extensive pond systems fish feed on the natural production of algae, plankton, invertebrates and small fish. After filling and stocking the ponds with fish water exchange is kept to a minimum to retain natural food organisms. Fertilizers and animal manures may be used to promote natural productivity. A trophic web of natural food organisms offers the opportunity for farmers to grow several different fish species, which feed on different ranges of prey organisms within the same pond environment. This practice of polyculture increases the production capacity of ponds and improves the use of available resources.

Table 2 Global production of major farmed freshwater fish and shellfish species in 2016.

Common name	Scientific name	2016 production (million tonnes)	2016 production (% of total)
Finfish			
Grass carp	<i>Ctenopharyngodon idellus</i>	6.1	11
Silver carp	<i>Hypophthalmichthys molitrix</i>	5.3	10
Common carp	<i>Cyprinus carpio</i>	4.6	8
Bighead carp	<i>Hypophthalmichthys nobilis</i>	3.5	7
Nile tilapia	<i>Oreochromis niloticus</i>	4.2	8
Atlantic salmon	<i>Salmo salar</i>	2.3	4

Picture 1 Floating cages used for growing tilapia line the banks of an irrigation canal in central Thailand.

Extensive fish culture may be fully integrated with field crop production to increase overall food yields. Fish culture in rice paddies is a traditional and growing practice in China, South East Asia and India. Fish are grown deep-water rice paddies, which are variously modified with open water channels to facilitate fish movements and harvesting. The rice paddies provide a rich diversity of food and shade for the fish and farmers are able to use less fertilizer for the same grain output.

Semi-intensive culture

Farmers can increase fish stocking density and output from semi-intensive pond systems where natural food is supplemented with agricultural by-products, such as rice bran. These are either consumed directly by fish or break down within the ponds and serve as sources of carbon, nitrogen and essential minerals to support the primary growth of phytoplankton.

Intensive culture

In more intensive culture methods there is decreased dependency on the availability of natural food and greater or total dependence on the use of complete feeds, formulated to meet the nutritional requirements of a particular fish species. There is a global trend in intensifying production methods in ponds (FAO, 2018). Farmers use more food and water resources but are able to grow fish at higher stocking densities and increase their yields (Goddard, 1996).

Freshwater Resources

Fish are farmed in ponds, cages and raceways, which permit sufficient water exchange to remove harmful waste metabolites and maintain the required water quality. Water for freshwater farming is drawn from lakes, rivers and springs or pumped from aquifers (Boyd, 2005). Fish farms in tropical and subtropical areas are subject to significant water loss from seepage and evaporation. In carp ponds in India the water exchange requirement has been estimated as 10.3 m^3 water kg^{-1} of fish produced, of which 7.6 m^3 is lost to seepage and evaporation (Sharma et al., 2013). Traditional trout farms in Europe and North America, which operate on through-flow systems, use much higher quantities of water to meet the more demanding water quality and dissolved oxygen requirements of trout. Some 30 m^3 of water are used to produce 1 kg of rainbow trout (*Oncorhynchus mykiss*) (Bregnballe, 2015).

Freshwater resources are under pressure from increased levels of abstraction for industrial and agricultural use linked to population growth. This contributes to water pollution, habitat degradation, flow modification and threatens the biodiversity of aquatic organisms. Around one third of the Earth's surface is defined as desert or arid (<200 mm rain annually). These regions generally lack food security and are vulnerable to the effects of climate change. In arid regions freshwater aquaculture using traditional methods is a marginal activity, yet one which can benefit in the future from water reuse technology (Goddard and Al-Abri, 2018).

Fish Farm Effluent and Waste Products

Effluent from all traditional fish farms, whether seasonal drainage from ponds during maintenance or continuous outflow from floating cages and intensive farms, carries waste in the form of fish metabolites, primarily ammonia and solid waste. If not treated or used to fertilize field crops fish farm effluent will promote eutrophication in receiving waters. Discharge of farm wastes into the environment is a limiting factor in the future expansion of traditional fish farming and in most regions is subject to strict environmental regulation.

Picture 2 Common carp (*Cyprinus carpio*). A widely distributed species of freshwater fish farmed in both temperate and tropical environments. Photo courtesy of Water Farmers, Canada.

Recirculating Aquaculture Systems (RAS)

Growing fish in RAS has a number of advantages compared with traditional pond and floating cage methods. Typically <10% of the water is required and the systems occupy a small percentage of the space required for pond culture. Since there is less dependence on natural resources farms can be located closer to population centers and markets for fish. RAS operate as closed, contained units, usually within buildings. They provide opportunity to maintain year-round optimal water quality and temperatures for particular fish species and support culture at high stocking densities (Colt, 2006). Full measures of biosecurity can be applied to control transmission of fish diseases and parasites and to prevent escapes of fish into surrounding waters.

The application of RAS technology has demonstrated key advantages for fish production in a controlled environment.

- Improved fish quality
- Enhanced growth rates
- Improved food conversion efficiency
- Improved biosecurity
- Reduced transmittable disease problems
- Lower use of therapeutants
- Management of waste and reduction of environmental impact

RAS Applications

Water recirculation technology and its application in aquaculture has seen considerable progress in recent years with standard methods emerging and equipment supplies becoming more available and cost efficient (Martins et al., 2010). Most of the current 80 million tonnes of global farmed fish is produced in open pond or floating net cage systems. RAS are currently used to produce <5% of this total but this figure is predicted to rise to 40% by 2030. RAS are used in various applications where benefits are gained from growing fish in a controlled environment. These include research facilities, fish hatcheries and food fish production facilities.

RAS fish hatcheries

Control of temperature and photo-period can be used to regulate fish breeding cycles and enable farmers to produce eggs and young fish for sale beyond the normal spawning season. RAS freshwater hatcheries are used to grow a broad range of species, both for farming and restocking natural waters. They are widely used for producing juvenile Atlantic salmon (*Salmo salar*) for stocking into sea cages.

RAS food fish

Whilst there is a general focus on the production of high-value food fish species RAS are also used to grow cheaper commodity species. There is current interest in the development of large cold-water RAS Atlantic salmon farms using either seawater or freshwater and each capable of producing many thousands of tonnes of fish per year. Marine cage farms for Atlantic salmon production discharge waste directly into the ocean and are subject to increasing environmental controls and licensing costs,

Picture 3 Sampling Nile tilapia (*Oreochromis niloticus*) from a RAS fish tank.

which may limit future expansion. In comparison RAS salmon farms can manage their waste to advantage and also control problems with sea lice. These are crustacean ectoparasites which damage fish and are difficult to control in the open ocean.

Warm-water species grown in commercial freshwater RAS include tilapia and African catfish (*Clarias gariepinus*). These fish grow rapidly at optimum temperatures and are tolerant of high stocking densities. Production costs are generally higher than those for fish produced in open systems and farmers seek benefits from economies of scale and siting their farms in close proximity to favorable markets (Picture 3).

Water Treatment in RAS

Waste products and metabolites, including feces, ammonia and carbon dioxide are released by fish and must be treated in water-recycling systems to avoid the accumulation of potentially harmful and toxic compounds (Fig. 1). A full description and illustrations of modern RAS are given in Bregnballe (2015).

Removal of solids

Feces and any uneaten food contribute to particulate solids which dissolve and break up in water into particles, with sizes ranging from $<001\ \mu\text{m}$ (dissolved solids) to $>100\ \mu\text{m}$ (settleable solids). High levels of solids are damaging to the delicate gills of fish and may cause physical injury, increasing the risk of bacterial infection.

Settleable and supra-colloidal solids form the bulk of solids excreted by fish and can be removed by gravitational devices and micro-screens. Circular fish tanks with flat bottoms are generally used in large installations. Water circulates uniformly and centripetal forces transport solid wastes to the center from where they can be separated in a small separate drain pipe from the main flow of cleaner water. Additional suspended solids can then be removed by a combination of swirl separators, radial flow filters or rotating drum filters fitted with micro-screens ($40\text{--}100\ \mu\text{m}$). The cleanest water is returned to the fish tanks, whilst waste-rich water is diverted for further treatment.

Biological filtration

Nitrogenous waste resulting from the metabolism of protein is excreted primarily as ammonia from the gills of fish. On release the free ammonia (NH_3) molecules react in water to form ammonium hydroxide, which readily dissociates into ammonium (NH_4^+) and hydroxyl ions (OH^-).

Nitrogen in the form of free ammonia (NH_3) is toxic to fish and is oxidized in biofilter structures by nitrifying bacteria to harmless nitrate growing in films in biofilters. Two major groups of autotrophic bacteria are involved in the oxidative process. *Nitrosomonas* convert ammonia to nitrite and *Nitrobacter* convert harmful nitrite to more harmless nitrate.

1. $2\text{NH}_4^+ + 3\text{O}_2 \rightarrow 2\text{NO}_2 + 2\text{H}_2\text{O} + 4\text{H}^+$ (*Nitrosomonas*)
2. $2\text{NO}_2 + \text{O}_2 \rightarrow 2\text{NO}_3$ (*Nitrobacter*)

Biofilters typically contain plastic media which are light to handle and provide a large surface for bacterial films to colonize. Moving bed bioreactors are commonly used. These comprise tanks containing small plastic bio-balls ($2\text{--}3\ \text{cm}$ diameter) with sculpted surfaces to provide maximum surface area. The biofilter media is submerged in the recycling water which is heavily aerated.

Fig. 1 Components and functions of a Recirculating Aquaculture System.

The size of biofilters is calculated based on various parameters. These include the total ammonia-nitrogen (TAN) released by the fish, hydraulic loading, water flow rates and the calculated surface area of the selected filter media. TAN calculations are based on the nitrogen content of the fish feed, daily food consumption, digestibility and nitrogen content of protein (Bregnballe, 2015).

Gas control

As water circulates through the fish tanks and biofilters oxygen is depleted and carbon dioxide accumulates. Aeration, using blown or compressed air linked to diffuser systems or airlifts can be used to increase oxygen levels. In RAS heavily stocked with fish oxygen gas is used to fully saturate the water with dissolved oxygen. Carbon dioxide is removed by heavy aeration in a process known as degassing.

pH adjustment

Within RAS the nitrification process produces acid which reduces the pH of circulating water. Water is dosed with a base compound, commonly sodium hydroxide, to restore pH to within the range 7.0–7.5.

Pathogen control

Ultra-violet light and ozone are used separately or in combination to reduce pathogen levels in the circulating water. UV tubes are commonly used and function by emitting light in wavelengths which destroy the DNA in biological organisms. Ozone functions by heavy oxidation of microorganisms and organic matter. Additionally it flocculates microparticles. These can be removed by physical filtration, clarifying the circulating water.

Waste water and sludge management

The solids separated from the circulating water can be de-watered and concentrated. Some 200 kg of solids (as dry matter) are produced for each tonne of food consumed by the fish. This waste can be used as an agricultural or garden fertilizer or as feed for biogas production.

Biofloc Technology

Extensive possibilities exist to conserve water through the novel application of biofloc technology (BT) (Avnimelech, 2009). Conventional RAS are mechanically complex and require significant amounts of energy. BT supports fish production in a much simpler system in which the harmful products of fish metabolism are processed by bacteria within the fish tanks or ponds (Avnimelech, 2007). BT enables farmers to minimize water exchange and water usage, whilst maintaining adequate water quality, through the balancing of carbon and nitrogen in the system (Crab et al., 2012). The technology is based on waste nutrient recycling, particularly nitrogen into microbial biomass. The biomass can be used directly as food by filter-feeding fish species such as tilapia and carp (Bossier and Ekasar, 2017) (Fig. 2).

Within ponds or tanks carbon: nitrogen ratios and dissolved oxygen levels are adjusted to provide optimal conditions for the growth of bioflocs. These are small aggregates (<1 mm diameter) of waste food, fecal material, phytoplankton, zooplankton and bacterial communities (Hargreaves, 2013). In well-balanced systems the bacterial communities take up the nitrogenous compounds, which are otherwise harmful to fish, and produce beneficial microbial proteins, lipids, vitamins and minerals.

Biofloc Farming Systems

Biofloc technology makes it possible to minimize water exchange and water use in fish farms; maintaining water quality whilst producing low-cost, protein-rich bioflocs. The practical application of biofloc technology in fish farming offers great potential for water conservation (Avnimelech, 2007). It is applied in static pond and tank systems and eliminates the requirement for water exchange in intensive culture systems. It is much simpler and less costly to operate than RAS. Microbial biomass contains 20–45% crude protein, 1–5% lipids (as dry matter), plus various bioactive compounds including essential fatty acids, carotenoids, vitamins and minerals (Kuhn et al., 2009). The availability of in situ nutrients has opened the way for reformulation of special aquafeeds for use in biofloc systems. Protein content can be reduced and fish meals can be replaced with plant meals. This improves sustainability and reduces cost (Martinez-Cordova et al., 2015). In practice Biofloc tanks or ponds must be continuously mixed and aerated and the carbon nitrogen ratio (C:N) carefully maintained (12:1-20:1) to support the formation and stabilization of a heterotrophic microbial community (Perez-Fuentes et al., 2016). Carbon content is balanced using readily available carbohydrate sources such as molasses or grain pellets. Total suspended solids content is monitored throughout the fish production cycle and maintained at optimal levels of 100–300 ppm. Excess biomass can be harvested and processed into feed ingredients (Kuhn et al., 2009).

Biofloc farming systems operate with zero or minimum water exchange and offer greatly enhanced biosecurity against the transmission of fish pathogens and parasites. Probiotics have been identified in bioflocs. These are microbial cells that have a beneficial effects on the health of a host organism, including growth promotion, increased immune response and inhibition of pathogenic microorganisms. The identification of natural probiotics and immunostimulants and their beneficial effects on fish survival and growth have been reported from recent studies on the microbial ecology of bioflocs (Rani et al., 2017).

Fig. 2 Inputs and products in a Biofloc Technology System.

Aquaponics

Aquaponics combines the benefits of fish production in modified RAS systems with the soil-less production of plants (hydroponics) using the same water. It operates within a closed-loop system where fish feed provides most of the nutrients required for healthy plant growth. These nutrients, excreted directly by the fish, or generated by the microbial breakdown of organic wastes, are absorbed by growing plants. Aquaponics was first developed in its modern form by scientists researching novel methods for treating recycled water in fish culture systems (Love et al., 2015). In these studies edible plants, such as tomatoes and lettuce, were used to remove waste products from carp and tilapia production tanks (Naegel, 1977). Current research is generally aimed at refining methods for improved integration of fish and vegetable production (Rakocy et al., 2006).

Water consumption is <10% of normal levels for horticultural production and can be provided from potable supplies or pathogen-free groundwater (Somerville et al., 2014). There are no direct mineral or fertilizer costs since the primary mineral source is the fish feed provided to support fish growth. Some small additions of alkaline salts to maintain a stable, neutral pH and ferrous salts to maintain the necessary iron content are the only mineral additives used in aquaponics. The intensive nature of aquaponic production greatly reduces the amount of land necessary for commercial production units and there is no requirement for arable land. The combination of aquaponics with modified water recirculation technology has opened the way for aquaponic developments on large commercial scale (Picture 4).

Integrating Crops

A wide range of vegetables and fruits are grown in aquaponic systems, including include lettuce, chard, pak choi, spinach, kale, basil, tomatoes, peppers and micro-greens. Two types of grow bed are commonly used for plant production.

Media-filled systems

Crops are planted in shallow grow beds (50 cm) which contain gravel or clay balls. Water circulation through the grow beds is maintained by a flood and ebb system, driven by a pump and controlled by a bell siphon. Each bed is filled with nutrient-rich water and drained 2–3 times each hour. The media provides a large surface area which promotes biological filtration, reducing ammonia to nitrite and nitrate. The media also provides support to plant root systems and enables relatively tall plants to be grown. The overall productivity of plants is generally less than in floating raft systems, although a greater range of vegetable and fruit varieties can be grown.

Deep water culture systems

This method is used for smaller plants such as herbs and salads, which grow floating in a styrofoam raft. The plants are initially contained in small coir pots and receive their necessary minerals from the fish tank via the water which circulates around their exposed roots which grow below the floating rafts. The fish are held in a separate tanks and water from the fish tank circulates continuously through the system. Beneficial bacteria live throughout the system and the extra volume of water in the grow beds provides a buffer for fish, reducing stress and potential water quality problems (Picture 2).

Deep water culture and media-bed systems may be used singly or in combination. Deep water culture methods are typically used in large commercial units for the production of large quantities of mono-crops, such as lettuce, kale, salad greens and culinary herbs.

Treated effluent from the fish tanks (blue) supplies nutrients to plants growing in media beds and deep water culture tanks. Photo courtesy of Water Farmers, Canada.

Fish Production

A limited range of freshwater fish species is grown in aquaponics. Tilapia (*Oreochromis* spp.) is most commonly grown since they are hardy, readily available, grow rapidly under optimal conditions and are familiar to consumers (Bernstein, 2013) (Picture 4). Other warm-water species include Asian seabass (*Lates calcarifer*), catfish (*Clarias* sp.) and common carp, including ornamental varieties of koi carp (Picture 3). The volume and value of food fish grown in aquaponics is small in comparison with plant production. Plants reach harvest faster, which permits multiple plantings and have higher value per unit weight than fish. Typically, profits are gained on plant yield rather than fish production, where fish are sold as a secondary crop and are used as a source of bio-available plant nutrients. An aquaponics farm producing 50 t of fish year⁻¹ can readily produce in excess of 1000 t of vegetables year⁻¹.

Planning

A detailed review of planning, construction, operation and economics of small-scale aquaponic farms has been provided by FAO (Somerville et al., 2014). Capital costs can be high in relation to income and a recent survey suggests that the majority of aquaponic farms operate on small commercial scale (Love et al., 2015). The fish culture units are typically small in comparison with commercial fish farms. The majority produce <5 t of fish per year per year (Love et al., 2015). Fish units of this capacity lack the economies of scale seen in commercial-size fish farms, where production capacities range from 100 to 1000 plus tonnes per year. Production costs for aquaponic fish may be higher, which necessitates careful planning to manage capital and operating costs of the fish unit and pursuit of favorable farm prices for fresh, local product.

Water Reuse and Treatment

The essential requirements for treatment of recycled water depend primarily on the plant growing system selected. Media-filled grow beds will filter some solids and function as biofilters. In contrast deep water culture systems require additional solids separation and biofiltration. Water flows from the fish tanks in a cycle through solids separation equipment, followed by biofilters and the plant grow beds. It is then collected in a sump, aerated and pumped back to the fish tanks. Additional air is supplied to the water circulating in deep water culture beds to maintain dissolved oxygen levels around the plant roots.

Metrics based on feed use are fundamental to aquaponics. Determination of the quantity and quality of food used daily are used to calculate both scope of water treatment necessary and the scale of hydroponic plant production which can be supported by the treated effluent from fish tanks. Calculating biofilter size should also take into account the available surface areas of the grow beds and styrofoam floats which will be in contact with water and will also support the growth of bacterial films. Routine monitoring of water chemistry is vital to maintain a balanced water reuse system (Colt, 2006). Recycled systems accumulate acidity which must be adjusted by base addition to maintain optimal pH for fish, bacteria and plants growing in the same system.

Food Safety

Food safety is a vital component of food production and aquaponic farmers must follow available codes of good practice and apply biosecurity protocols for both aquaculture and horticulture components. The bacterium *Escherichia coli* is the most widely studied potential contaminant in aquaponics. This bacterium is found in the intestines of warm-blooded animals, including birds and cattle, and has been used in developing human health-based regulatory standards as a common indicator of fecal contamination and microbial water quality in agricultural water systems. Indicator microbes and pathogenic bacteria, such as *E. coli* and *Salmonella* spp., if present in aquaponic systems, most probably originate from warm-blooded animals, such as birds, since these enteric bacteria are transient in fish gut microflora (Sugita et al., 1996). As in all crop production systems cross-contamination is possible. However, the risk in aquaponics farming systems is low when compared with the traditional production of field crops (Sirsat and Neal, 2013). Extensive studies have reported negative tests from aquaponic farms for the food safety indicator organisms *E. coli* and *Salmonella* spp. (Chalmers, 2004, Fox et al., 2012).

Urban Aquaponics

Disused industrial space, including rooftops, is attracting aquaponics development in many European and North American cities. These typically use temperature and light-controlled greenhouse structures designed to support year-round production and incorporate space-saving stacked and vertical horticulture systems. Capital and operating costs are high but operators benefit from a large consumer base and demand for local, organically-produced fresh products. Urban projects play an important role in education and public awareness of food sources and security.

Prospects

Freshwater fish farming is predicted to expand into the future as farmers intensify their existing production methods. The annual rate of growth is slowing however, water resources are limited and new applications of more sustainable technologies are needed.

The sector faces the challenge of climate change. Erratic climate patterns of draught and flooding have direct physical impacts on traditional farms. Temperature changes, including heatwaves and abnormally cold events affect survival, reproduction and growth patterns of fish and may promote the spread of fish parasites and pathogens (Bueno and Soto, 2017). The development of closed systems, such as RAS, BT and aquaponic farms with enhanced biosecurity will help mitigate these risks.

It is important to control energy costs in closed-system aquaculture. Many farmers currently use renewable sources to power necessary equipment and it is expected that this practice will become universal within the next decade.

Integration of aquaponics with biofloc technologies has the potential to reduce the costs of water treatment, improve feeding efficiency and scale-up fish production. Early research indicates the bio-availability of plant nutrients in biofloc tanks and ponds (Pinho et al., 2017). Present systems will require modification for efficient handling of solids waste and excess biofloc.

Potential exists to apply aquaponic techniques in arid regions where salinization of ground water restricts traditional agriculture. Many farmed fish species are tolerant of low to medium salinities and their production can be combined with growing salt tolerant varieties of traditional crops at low salinities (Goddard et al., 2010) or edible halophytes at higher salinities (Pantarella and Bhujel, 2015).

Abstract

This article reviews the basics of mining and its interaction with water resources. While mining often requires a large amount of water, it can also present various risks to water resources, such as depletion or pollution (especially if acid and metalliferous drainage related to iron sulfide minerals to the surface environment). Modern mining is typically regulated to address these risks, with statutory environmental reporting increasingly being made public to improve transparency and align with the need for industry-wide reporting on sustainable development performance. The article presents a concise overview of mining, its interactions with water resources, key risks to manage, and the principal regulatory and reporting approaches which can be used for sustainable management of both mining and water resources.

Introduction

Mining and water resources are intimately linked but have a complex and often fraught, poorly understood relationship. In simple terms, the process of mining requires significant amounts of water but can also manifest substantial risks to surface, marine and groundwater resources as well as the ecosystems and communities which depend on these water resources—analogueous to agriculture and other human activities. This complex picture for mining has been recognized for millennia, with the great Middle Ages mining scholar Georgius Agricola famously writing in his final treatise “De Re Metallica” that:

... the strongest argument of the detractors is that the fields are devastated by mining operations ... Further, when the ores are washed, the water which has been used poisons the brooks and streams, and either destroys the fish or drives them away. Therefore the inhabitants of these regions, on account of the devastation of their fields, woods, groves, brooks and rivers, find great difficulty in procuring the necessities of life, and by reason of the destruction of the timber they are forced to greater expense in erecting buildings. Thus it is said, it is clear to all that there is greater detriment from mining than the value of the metals which the mining produces. (Agricola, 1556, p. 8)

It has therefore been clear for centuries that mining can cause significant impacts to water resources, ecosystems and communities—that is, in more modern language, mining can lead to unsustainable outcomes if such risks are not identified, mitigated and managed well. This is the crux of mining in the 21st century but the scale is no longer very small scale mines affecting very localized catchments, as in Agricola’s Erzgebirge region (the “Ore Mountains” of Saxony) but rather often giant sized mines operating in almost every reach of the earth (Antarctica being the only exception where mining is banned by international treaty). In some parts of the world there are now great mining fields with numerous giant mines—such as the Mpumalanga coal province in South Africa, the lead-zinc and copper mines of Peru, the copper mines of the Atacama Desert in Chile, the iron ore mines of the Pilbara region in Australia or the Nevada gold fields of the United States (amongst many others). This leads to the need to consider not just one mine with respect to water resources but the cumulative effects of many mines in a geographic region or water catchment—effects which have to be considered alongside other activities in a catchment such as agriculture, environmental water flows, urban centers, and so on. There is also an increasing need to consider the climate change risks to water resources as well as the impacts of climate variability (which can be further exacerbated by climate change).

It is also important to remember, as the old saying goes, “if it aint grown, it’s mined”—meaning that society needs the materials provided by mining just as much as they need food and water. In the 21st century the modern world needs an ever-increasingly

complex suite of raw materials which mining provides—from the staples of iron (for steel) to light and base metals (e.g. aluminum, copper, zinc, nickel, etc.) to the so-called critical metals which are crucial for modern technology (e.g. rare earths, indium, lithium, tellurium, rhenium, etc.). When combined with population growth and economic development across the world (especially increased consumption and urbanization), this leads to an ever-growing demand for the raw materials which mining provides.

This article will review the basics of how mining works, the use of water in mining, the types of water resources impacts that mining can cause (especially water pollution), approaches to water management and reporting in mining, and finally present some important case studies. It is intended to present a broad coverage of the primary issues between water resources and mining, with greater detail found in the literature.

The Brief Basics of Mining

The extraction of raw materials from the earth, known as mining, typically involves several steps, depending on the element of interest. First, a sufficiently rich deposit must be located and explored to assess whether it is worth the costly process of mining. Second, assuming a deposit is considered economic and approved for extraction, a mine is built and operated. Typically, the products of a mine, such as a concentrate or saleable ore product, require further processing in a smelter and/or refinery to produce a metal suitable for sale to manufacturing. Smelters and refineries are commonly a long distance away from the mine (e.g. another country and often far away). Finally, after a deposit is exhausted or becomes uneconomic, a mine is expected to be rehabilitated to a suitable ecological standard. This is often known as the mining cycle, since there is a need to continually find more deposits to meet ever-growing global demand for raw materials.

Within a mine, there are typically two principal stages—mining and processing. The material with economic concentrations of metal(s) (or minerals) of interest is known as ore, which can be extracted through an open cut or underground mine. An open cut mine involves digging a large hole or void to access the ore, necessitating the extraction of large amounts of waste rock (sometimes called overburden) in the process. An underground mine uses shafts or tunnels to target and access ore, through a variety of methods (e.g. narrow vein, stoping, caving, etc.), leading to minimal amounts of waste rock. The processing stage involves using a particular technology to extract the metal or mineral of interest. Before any direct processing occurs, the ore is usually ground to a fine powder to increase the ability of separation. For base metals, such as copper, lead, zinc, nickel, a process known as flotation is used which preferentially concentrates the sulfide minerals containing the metals into a much smaller volume, with the product known as a concentrate. For certain metals, leaching processes can be used for direct extraction, such as using cyanide for gold or sulfuric acid for uranium. For bulk minerals, processes involving gravity or magnetic separation can be used to produce a saleable ore (e.g. iron ore, bauxite, manganese). The concentrates or saleable ores are then further processed at a smelter and/or refinery to produce a pure metal (or mineral in some cases).

Furthermore, there are also other techniques of mining which rely on the use of solutions directly in mining and their processing to produce a metal directly at the mine with no need for subsequent smelting or refining. For some metals, a mine can process ore using heap leaching, whereby ore is stacked into large piles, irrigated with a solution which has a chemical added to facilitate leaching and extraction (e.g. sulfuric acid or cyanide), and the rich solution from the bottom of the heap is then processed for the metal of interest. The use of heap leaching is widespread in the copper and gold mining sectors, with an increasing number of examples in other sectors (e.g. uranium, zinc, nickel). Alternatively, if the ore zone is sufficiently permeable, the reagent-rich solution can be directly injected into the ore to leach the metal(s) of interest and then pumped back to the surface for processing—a mining method known as “in-situ leaching” (ISL). Although there are some similarities between ISL and the petroleum industry, namely solution flow through a deposit of interest, there are also key differences. For example, conventional petroleum does not require primary chemicals to facilitate oil and gas extraction, although unconventional petroleum extraction from shales requires the use of hydraulic fracturing (aka “fracking”) and a range of chemicals to facilitate this.

Overall, the essential steps involved in mining include the extraction stage (via open cut or underground methods), the ore processing stage and finally the smelting and/refining steps to produce the metals (minerals) of interest. Alternatively, solution-based methods can also be used. It is therefore important to understand the exact configuration of any mining project, as this helps to identify and manage various risks to water resources.

As an example, the Chuquibambilla copper-molybdenum field in northern Chile is shown in Fig. 1, highlighting the various features of the mining complex.

Water Use in Mining

It is perhaps obvious to state that mining requires a significant amount of water to operate, but it is certainly not obvious that there is wide-ranging complexity and variability in how much water may be used for a given mining project—even for mines of similar scale and configuration. There are a variety of water needs in mining, such as:

- Mining—water for suppression of dust (especially for open cut mining);
- Crushing-Grinding of Ore—the crushing and grinding of ore to a fine powder generates vast amounts of dust which need control via water sprays;

Fig. 1 The Chuquicamata copper-molybdenum-silver-gold field of northern Chile, showing the various mining features (*red*—tailings dams; *blue*—waste rock dumps; *yellow*—open cut mines; *green*—heap leach piles; *white*—processing facilities), the adjacent town of Calama (*bottom center*) and the River Loa (*right and along bottom*) (note the large tailings dam area is approximately 12 km wide). Figure adapted from Google Earth Service.

- Ore processing: finely sized ore is typically mixed with water to allow processing, such as flotation or leaching technology;
- Tailings disposal—after separation of metals (or minerals), the residual material is known as tailings and is commonly pumped as a slurry to an engineered tailings storage facility (or dam);
- Environmental management—including discharges of appropriate water to maintain environmental flows in streams, or for revegetation and rehabilitation works;
- Drinking water—for mine workers on site and sometimes the nearby mining town also.

The two dominant sources of water that a mine will access are surface water and groundwater, with sea (or marine) water used in rare cases (e.g. direct use or for a desalination plant to produce fresh water). Furthermore, it is important to consider the quality of different water sources, such as fresh, brackish, saline or hypersaline, as well as the interactions between the various water resources. All mines operate within a climatic context, such as temperate, tropical, arid or hyper-arid climates with widely varying seasonal temperature regimes (e.g. the Köppen-Geiger climate classification system). Finally, mines also operate within a regulatory context which will vary all over the world, and a mine's water management system will be tailored to meet these statutory requirements (such as the amounts, quality and timing of mine-related water discharges to streams, if allowed at all), as well as potentially any local social and environmental factors which need to be linked to a mine (e.g. maintaining environmental flows, protecting water quality, ensuring water availability for other users such as farmers, etc.). Overall, mining can be a very large user of water but the details are important and always very site-specific to assess and understand.

Water Resources Impacts From Mining

Surface Water Resources

Historically, mining was a modest affair and occupied a small extent of land—but modern mining can be vast in scale and occupy large tracts of land. With respect to surface water resources, this means that the risks and interactions are now much larger and more significant. There are many types of surface water impacts which mining can cause, such as (e.g. [Da Rosa et al., 1997](#); [Spitz and Trudinger, 2008](#)):

- *Stream diversions*—mining can necessitate the diversion of streams, ranging in scale from small creeks to large, long diversions (e.g. the McArthur River zinc and numerous coal mines in Australia);

- *Altered catchments*—mining causes significant geomorphological changes to hydrological catchments, due to open cut mines, waste rock dumps, ponds, tailings dams, process plants and infrastructure—leading to changes in runoff characteristics and surface water flows;
- *Extraction*—surface water can be extracted for use in mining, reducing stream flows;
- *Discharges*—a mine can sometimes discharge accumulated waters to adjacent streams, sometimes altering flow regimes and associated environmental and cultural values (e.g. Weeli Wolli Creek, Pilbara iron ore mines, Australia);
- *Contaminants*—waters (and sometimes sediment) leaving a mine site and entering a stream can carry contaminants which can cause impacts from short-term changes to water quality to severe pollution and aquatic ecosystem impacts, often associated with acid and metalliferous drainage (“AMD”, more commonly known as acid mine drainage).

All mines will have a water management plan which should address all of the above risks, meaning that the extent of actual impacts will vary considerably. For example, mines in tropical, high rainfall zones will have an excess amount of water which is often discharged. Conversely, mines in arid to hyper-arid climates will often face water deficits and need to manage water use very efficiently. In parallel, all mines will need to manage water quality, with criteria typically set by a government regulator and associated water resources policies or guidelines. In some cases, water with poor quality will need to be treated before it could be re-used or discharged. Various treatment methods are used across the industry for this, including reverse osmosis, engineered wetlands, land application (or irrigation), mixing with other water streams, or in some cases discharge to a nearby stream under strict criteria of high flows to maximize dilution (although this latter option does not address bioaccumulation risks from heavy metals or other contaminants).

Groundwater Resources

Groundwater is the water contained in saturated media below the ground surface, the study of which is a discipline known as hydrogeology. For groundwater, where it can be extracted from a geological layer or formation at a reasonable rate, this is called an aquifer (e.g. sands, sandstone, limestone). A geological layer or formation which limits the flow of water through it is called an aquitard (e.g. clays, shales). Given the often large extent of open cut mines and the scale and increasing depth of underground mining, groundwater presents various issues for mining, including:

- *Depletion*—open cut and underground mining require the extraction of groundwater, for both safety and access, with the amount depending on the scale of mining as well as the local and regional hydrogeological context, such as a productive aquifer (or the presence of aquitards);
- *Contaminants*—the seepage of waters from ponds and tailings dams (or in some cases direct injection) can carry contaminants into the underlying groundwater system, leading to impacts from short-term changes to water quality to severe pollution, often associated with AMD.

As with surface water, a mine should have a major focus on groundwater issues in its mine water management plan. For most mines the focus will be on monitoring the levels (or heads) and water quality groundwater to assess the impacts and risks from mining. For mines which use groundwater as their primary water source, they will also need to monitor this extraction carefully, which can often be at some distance away from the mine.

Marine Water Resources

Mining typically has very little interactions with marine water resources, mainly due to the fact that most mining occurs inland away from coasts and the marine environment. However, mining effects on stream flows and quality may reach the marine environment, especially if direct discharges occur. This remains a key concern for the coal mines of the Bowen Basin in central Queensland, Australia, as their collective discharges enter the Fitzroy River—which flows into the marine environment of the Great Barrier Reef (other impacts also need to be considered, such as agriculture, urban centers and other land uses which may also affect the Fitzroy River).

In some circumstances, mining can occur on the coast and impacts to marine water resources can be a real risk. For example, the Lihir mine in Papua New Guinea (PNG) mines a large gold deposit by open cut on the coast of a small island. Given the void is well below sea level, the mine induces the flow of sea water through the aquifer and this water is then discharged back to sea. Furthermore, waste rock from the mine is emplaced in the shallow harbor adjacent to the mine, with tailings discharged at depth to the marine environment (see later).

A frontier issue is the growing interest in the extraction of mineral resources from the deep-sea floor, ranging from volcanic sulfide vents, to manganese nodules or mineral rich sediments on seafloor mounts. The typical water depths can range from 1.5–2 km (e.g. vents, mounts) to 5–6 km (e.g. nodules). Deep sea mining has never been done before on a commercial scale, with trial mining recently completed in Japan’s deep marine waters and a proposed mining project at Solwara in PNG (which is currently in stasis given the lead company, Nautilus Resources, is working towards re-financing its debts). There are many complex issues which remain unresolved with potential deep sea mining, including marine biodiversity impacts—and especially the interaction of shallow, intermediate and deep sea biota, sedimentation issues from mine wastes, impacts to marine water quality and the difficulty of mine rehabilitation in deep waters.

Acid and Metalliferous Drainage (“AMD”)

The greatest water resources risk from mining is, without doubt, polluted mine water known as acid and metalliferous drainage (“AMD”)—commonly known as acid mine drainage. This is formed from the weathering of iron sulfide-related minerals in tailings or waste rock, and sometimes even from open cut mine walls or underground voids, leading to the formation of acidic, saline and/or heavy metal-rich waters which present a severe risk to aquatic ecosystems and human use of AMD-impacted waters. In recognition of AMD risks in particular, the US Environmental Protection Agency is attributed as stating in 1987 that (as cited by [EEB, 2000](#)):

... problems related to mining waste may be rated as second only to global warming and stratospheric ozone depletion in terms of ecological risk. The release to the environment of mining waste can result in profound, generally irreversible destruction of ecosystems.

The geochemistry of AMD is both simple and complex—in other words, although it can be simplified it is always site-specific with lots of factors to consider. In essence, AMD is caused by the exposure of iron sulfide minerals, such as pyrite and its close cousins, to water and oxygen. In general, AMD is considered to be a three-stage process, involving iron sulfide oxidation, then oxidation of ferrous to ferric iron (Fe^{2+} to Fe^{3+}) and the ferric iron either precipitating as ferrihydrite or further oxidizing sulfide minerals (e.g. [Lottermoser, 2010](#)). The overall reaction can be represented as:

(or in words : pyrite + oxygen + water goes to ferrihydrite (aka rust) + sulfuric acid + heat)

The sulfuric acid can then dissolve other salts and heavy metals, leading to extremely high concentrations in AMD-affected waters. In some cases, the acid can be buffered by alkaline minerals such as carbonates, leading to a pH neutral water but still rich in salts and heavy metals—hence AMD is more accurately called “acid and metalliferous drainage,” to reflect examples of neutral, saline and or/metalliferous drainage (e.g. [Taylor and Pape, 2007](#)). Examples of the chemistry of AMD at some mines are shown in [Table 1](#), including Australia’s water quality guidelines for high conservation value streams (Australia’s guidelines can be substituted for any equivalent national requirements or comparison to drinking water standards in the absence of specific environmental guidelines). Stark visual examples of AMD-impacted streams are shown in [Fig. 2](#).

Table 1 Selected examples of the chemistry of acid and metalliferous drainage (AMD) and comparison to Australia’s water quality guidelines (all mg/L, except pH; where given, number of samples on brackets).

Fig. 2 Examples of acid and metalliferous drainage (AMD) impacts on water resources.

There are lots of site-specific factors to consider in assessing the risks of AMD generation, including particle and pore size of waste materials (e.g. coarse waste rock versus fine tailings), crystal and mineral structures (weaknesses increase oxidation), trace element substitution in sulfides (making it easier for oxidation), other mineralogy (especially other sulfides and alkaline minerals), temperature (hotter increases the oxidation rate), presence of microorganisms (especially acid- and heat-loving bacteria which thrive on iron oxidation, vastly speeding up sulfide oxidation rates), extent of oxygen and water availability (i.e. low availability limits the overall reaction progress), climate and hydrological seasons (e.g. wet/dry seasons), amongst others (see [Blowes et al., 2014](#); [Da Rosa et al., 1997](#); [Lottermoser, 2010](#); [Spitz and Trudinger, 2008](#); [Taylor and Pape, 2007](#)).

Across the world, there are many mines or regions which are now well recognized for their AMD-impacted catchments. An incomplete list includes the Witwatersrand gold and Mpumalanga coal fields of South Africa, the Tinto region of southern Spain (the namesake site for the Rio Tinto Ltd./Plc mining company), Mount Lyell, Mount Morgan and many others in Australia, the Sudbury Basin in Canada, Butte in Montana, USA, the Milluni Basin in Bolivia, amongst many, many others. Overall, there is (unfortunately) abundant field evidence to support the US EPA's statement of environmental risks from mine wastes—which largely revolve around AMD-related risks to water resources and aquatic ecosystems.

Water Management and Reporting in Mining

There have been a variety of approaches which have emerged since the late 1990s to facilitate reporting on the water aspects of mining—namely statutory environmental reporting or sustainability focussed reporting. While each approach has their merits, only the broad approaches are discussed here.

From about 1970 onwards, many countries around the world enacted legislation to protect the environment, led by the introduction of the National Environmental Policy Act 1969 in the United States which established the federal Environmental Protection Agency. In general, this limited the discharge of pollutants to the environment and allowed the establishment of standards for air, water and soil quality (especially for the remediation of formerly contaminated sites). From the 1980s to 1990s, this had evolved from licensing to monitoring and reporting on performance against environmental standards. That is, although a project may have an environmental permit for their discharges, they also needed to monitor the environment and ensure that their operations were not causing impacts which exceeded specific standards. This type of monitoring and reporting, typically done annually, has become known as statutory environmental reporting, and can be a very powerful mechanism to synthesize and publish monitoring data, especially over repeated years. For example, in the state of New South Wales, Australia, statutory environmental reports are required to be made publicly available for all mining projects by the company (e.g. their website). Over time, this allows evidence to be published about the actual impacts a mining project may or may not be having on the environment. Water resources remain a fundamental area of concern for such reporting (along with air quality, biodiversity, noise, mine waste, etc.).

In 1997, the Global Reporting Initiative (GRI) was developed to facilitate a more comprehensive reporting of the contribution to sustainable development by any type of organization as well as to give sustainability reporting the same profile and importance as statutory financial reporting. The GRI had metrics or indicators to report on various environmental, social, human rights, economic and financial aspects, evolving from the first “exposure draft” in 1999 through four formal editions to become a standard as of 2016. Although some global mining companies had pioneered the preparation of environmental progress-type reporting in the mid-1990s (which included energy, chemicals and water use and greenhouse gas emissions), following the 2002 United Nations Earth Summit in Johannesburg, South Africa, the global mining industry adopted the need for sustainability reporting—the basis of which quickly became the GRI. From large to small mining companies, GRI-based reporting is now becoming as prominent and common as financial reporting, helping to shine a light on the environmental, social and economic performance of mining companies.

Under the GRI, key aspects of water were reported, including water consumed, recycled water, water sources and discharges to water resources. Early water data reported for mines through GRI-based reports was highly variable and at times inconsistent (see [Mudd, 2008](#)), leading the Australian mining industry to develop the “Water Accounting Framework” (WAF) to facilitate standardized reporting that matched the GRI requirements ([SMI and MCA, 2012](#)). The WAF was recently extended to a global standard by the International Council on Mining and Metals (ICMM), ensuring global consistency on water data reported by the mining sector since ICMM members are required to implement such measures ([ICMM, 2017](#)). The example of detailed water reporting for the Diavik diamond mine in Canada is shown in [Fig. 3](#), highlighting the aspects reported and of concern to local indigenous communities.

Case Studies

Lady Annie Disaster, Australia

In early 2009, there was a very large environmental accident at the Lady Annie copper mine, about 200 km northwest of Mount Isa in western Queensland, Australia. The project was a new heap leach mine which used acid solutions passing through piles (or heaps) of copper ore to dissolve and extract the copper to be purified in a chemical refinery. Commercial operations started in October 2007, at the height of the mining boom. By late 2008, global metals prices had crashed, due to the evolving global financial

crisis and the project became uneconomic, followed by bankruptcy placement for the operating company, CopperCo. Rainfall was high in the early months of 2009, leading to considerable local flooding onsite and eventually a structural failure of the solution ponds. Highly acidic and metal-rich solutions flowed into Saga and Inca Creeks, part of the headwaters for the Buckley River, one of the Lake Eyre Basin's major western river systems. At least 447 ML of mining waste water was accidentally released during two periods in early 2009, severely degrading water quality, biodiversity (killing fish in particular), pastoral grazing (including dissolving steel fences and cattle being put down) as well as recreational and indigenous values for the streams (Taylor and Little, 2013). The mining company was convicted of serious environmental harm and fined half a million dollars, with the additional responsibility of remediation and engineering costs of almost \$11 million. Although the mining company was explicitly alerted to this risk by the regulator before the accident, nothing was done to prevent it.

Cadia Valley Operations, Australia

The Cadia Valley Operations, just west of Sydney in central New South Wales, Australia, is a complex of three large gold-copper-silver mining projects and a central processing mill. The use of water and potential impacts on surface water and groundwater resources has always raised controversy since it began operations in August 1998. Newcrest Mining, the operator of Cadia, has been publishing the site's statutory environmental management reports for over a decade, and was an early pilot site for the WAF. The Cadia site has a comprehensive water management system, and includes surface water (licensed allocations), groundwater extraction from mine operations, treated effluent from nearby sewage treatment facilities as well as extensive recycling of water from the tailings dams. The extent of water from each source will vary each year depending on climatic conditions (e.g. drought), water needs and availability. The use of water in the processing mill is shown in Fig. 4, highlighting the seasonal variability (i.e. typically higher in summer months), the long-term very gradual increase in water use but also the difference in using monthly mill data (which effectively represents total water use) versus imported surface water (the dotted line). In May 2007, due to the decade-long severe drought across eastern Australia, the Cadia operations were almost forced to close due to lack of water security—with the rains in June 2007 breaking the drought.

Tailings Dams and Waste Rock Management

Tailings are the finely ground rock material remaining after the metals (or minerals) of interest have been extracted. Typically, tailings are pumped as a slurry to a storage dam, following similar engineering principles to water storage and hydroelectric dams. That is, a tailings dam has to be designed and engineered to address risks such as flooding (e.g. 1-in-100 or 1-in-1000 year storm events), seismic events (especially in some parts of the world), geology and geotechnical conditions (i.e. physical stability), seepage

Fig. 4 Cadia water use per tonne of ore processed over time. Data from Newcrest Mining Ltd—Annual Environmental Management Reports (various years).

to groundwater and eventual closure and rehabilitation. In higher rainfall climates, tailings dams may need to incorporate a spillway to discharge excess waters and/or active water treatment (especially if reagents such as cyanide are used). A mine will typically build a tailings dam in stages, expanding the capacity as operations progress. Some tailings dams are now storing more than a billion tonnes already, meaning they can be truly giant facilities (as shown in Fig. 1 earlier). Waste rock is the material which has to be extracted to mine the metal-rich ores and is often multiples of the ore processed annually (see scale of waste rock areas in Fig. 1). The world currently produces at least eight and eighty billion tonnes of tailings and waste rock every year, respectively (author's estimates).

At a very select few sites around the world, tailings are allowed to be discharged into rivers or the marine environment—a practice which has largely been banned for many decades in most countries. At the Ok Tedi and Porgera (PNG) and Grasberg (Indonesia) mines, some 20, 6 and 60 million tonnes (Mt) of tailings, respectively, are discharged to rivers every year (plus a large fraction of about 40, 20 and 125 Mt./year of waste rock, respectively, either directly erodes or indirectly will erode also). The impacts of this practice are extreme, resulting in changed geomorphology and changed flooding regimes (especially on the floodplains downstream of the mines), significant impacts on the biodiversity as well as social impacts from the impacts on water resources. Alternatively, some mines deposit tailings directly into the marine environment (e.g. from 120 m depth) to avoid the impacts of riverine tailings disposal and costs and risks of engineered dams. At the Lihir mine (PNG), which sits on the edge of a remote and very small island, ~14 Mt./year tailings are now discharged to the deep sea while ~15 Mt./year of waste rock are emplaced in the shallow waters of Luise Harbour. At Batu Hijau, Indonesia, ~40 Mt./year of tailings are discharged to the deep sea. A small number of modest-scale mines in Norway and Turkey also practice marine disposal of tailings.

Unfortunately, there are many examples where tailings dams have failed and caused catastrophic disasters (e.g. environmental pollution, ecosystem damage, loss of life). The most high-profile examples are the two disasters in Brazil at the Samarco and Córrego do Feijão iron ore mines in 2014 and 2019, respectively, as well as the Mount Polley copper-gold mine in Canada in 2014. While the causes of each failure are always site-specific, common themes always emerge around poor site investigation, inappropriate engineering design, lack of risk assessment (especially consequence analysis) or deficient dam construction, operation and/or closure (often to save costs). Without doubt, all failures are absolutely preventable—but every tailings dam needs a comprehensive approach to all stages, from planning and design to construction and operation and eventually closure and rehabilitation (e.g. Franks et al., 2011). Recent disasters have highlighted the fundamental need for strong technical oversight, not just by mining companies and their consultants but especially government regulators.

Summary

Mining can be a large consumer of water and present significant and long-term risks to surface, marine and groundwater resources. Major pollution risks such as acidic and metalliferous drainage (AMD) have been observed for millennia, but it is only with the recent substantial growth in global mining that the scale has become so large that entire catchments may be affected. Modern mining is typically regulated by how much and what sources of water it can use as well as protecting water quality, with mines and companies adopting complex and varying water management approaches. The principal risks which need to be clearly identified for management include water depletion, groundwater and surface water interactions, water quality impacts but especially pollution risks from AMD which can continue for decades to centuries (or more in some cases). In addition, climate variability and the expected trends of climate change need to be factored into the water management system for a given mine and its environmental and social context. Finally, the digital age is facilitating public reporting and transparency around the ways that mines use water and may or may not impact water resources. This is crucial in modern, sustainable management of both mining and water resources as it helps to address community concerns and regulatory and investor or shareholder needs (especially in the context of ethical or responsible investment).

Abstract

Industries require large amounts of water which are used by various industries around the world at different rates and in different ways. Global water consumption has consistently been increasing since the 1980s and is expected to continue due to rising demands. Currently industrial water consumption is described as a major drain on the world's limited water supply and it is expected that the water demand will exceed current supply by 40% by 2030. The use of water for industrial processes as well as the discarding of wastewater can have various impacts if not properly managed and controlled. The continued increase of industrial water use accompanied by continued population and socio-economic growth will consequently exacerbate current effects of industrial water use and cause greater future challenges. Industries are a huge source of pollution around the world as they produce pollutants which can be very harmful to both the environment and the human population. Freshwater resources around the world are faced with significant pollution problems, some more than others. The expanding industrial base with accompanied pollution have placed additional pressure on existing water and often causes water resources to no longer be suitable for human consumption or other uses. Water is at increased risk worldwide and industrial sectors will have to implement various strategies to minimize this risk in the future.

Industrial Water Use

Industrial water use includes that used by economic entities such as mines, oil refineries, manufacturing plants, as well as energy installations using water for the cooling of power plants (WBCSD, 2006). It is mainly characterized by water being used in the production process (e.g. cooling purposes, cleaning/washing and employee use) and ultimately involves the manufacturing of a product. Water is vital in this sector as it helps machinery used in the production process to run efficiently and can also be a vital part of the product itself such as in the case of beverages. Industrial water is ultimately used for fabricating, processing, washing, diluting, cooling or transporting of a product. It is also used by smelting facilities, petroleum refineries, industries producing chemical products, food, paper and chemicals.

Industries require large amounts of water. Machinery requires cooling to a temperature which allows continuous manufacturing. The mining industry is also dependent on water in terms of washing of material brought up from underground to sort out the genuine product from the other particles. Water is also used for dust control as in the case of surface mining operations. Machinery and buildings are cleaned and in the case of the meat industry, water is used to process or trim animal carcasses.

Vast amounts of water are used in oil producing regions especially when oil wells are old and the underlying oil reserve has been tapped. Water is pumped down into the oil formation to push oil out. This industrial use of water has played a major role in this industry, without it oil and petroleum would be more scarce and expensive. Power generation also makes use of water through cooling equipment and to push turbines which forms the core of the electricity production process. Surface water resources are the most commonly used sources and much of the water is eventually returned to the environment for re-use. The pulp and paper industry also uses millions of liters of clean water especially in the papermaking process. Clean water is required to ensure that paper is smooth and that the machinery is not damaged by solid particles. Water may not play a key part in making the actual product in other industries however it is nevertheless required such as in the case of the steel making industry where water is used to cool equipment.

Water is therefore used by various industries around the world at different rates and in different ways. The following section will focus on the current and future observed trends of industrial water use in terms of consumption and withdrawal.

Current and Future Trends in Industrial Water Consumption and Withdrawal

Global water consumption has been increasing 1% per year since the 1980s and has been driven by a combination of continued population growth, socio-economic development as well as changing consumption patterns (Fig. 1). The global water demand is expected to continue to increase at a similar rate until 2050. An increase of 20–30% above the current level of water use is projected and is attributed to continuous rising demands in the industrial and domestic sectors (OECD, 2012; Burek et al., 2016; IEA, 2016). It is predicted that water use by the agricultural sector will likely fall in comparison with other sectors. However, it will remain the largest overall user in the coming decades in terms of both water withdrawal and consumption (WWAP, 2019).

Currently, industrial water use, which includes power generation, accounts for 20% of global water consumption and there are indications that this demand will rise. Although the industrial sector uses significantly less than the agricultural sector, the growth in water consumption has been rapid and global withdrawals quadrupled between 1950 and 1995 (Rosegrant et al., 2002; WWAP, 2019). Industrial water use is the second largest user of water globally and varies significantly from one type of industry to another. Water is used for energy in terms of hydro projects, cooling water for thermal power generation, process water, water for products and in some cases for waste disposal to name but a few. In the industrial sector, business is largely dependent on water, meaning that limiting water means limiting business (du Plessis, 2019).

Freshwater withdrawals have tripled over the past five decades with water demand increasing by 64 billion cubic meters per year. Currently industrial water consumption is described as a major drain on the world's limited water supply and it is expected that the water demand is expected to exceed current supply by 40% by 2030 (Schelmetic, 2012). The industrial era has mostly been characterized by water being viewed as a free and/or low-cost commodity. But, this perception is rapidly changing as communities across the globe are confronted by water supply limitations (Byers et al., 2010).

Industrial water use varies across the globe. Industrialized or developed nations are characterized by higher industrial water use, whereby they consume more than half of water available for human consumption. As much as 45% of water demand is generated by industries in advanced economies (Rosegrant et al., 2002). The percentage of industrial water use therefore varies significantly on a regional level according to the level of development (Fig. 2).

There is a current movement of more nations becoming more industrialized mainly attributed to global economic growth which is fuelling the expansion. Industrial water use will therefore grow much faster in developing countries than in developed countries and can have far reaching consequences. It is estimated that industrial water demand will increase to 121.7 cubic kilometers in 2025, seven cubic kilometers more than in the developed world. The intensity level of industrial water use is estimated to decrease on a global level as a result of improvements in water-saving technology and demand policy. However the absolute size of the increase in the world's production will still lead to a total increase in industrial water demand (Rosegrant et al., 2002).

The largest single use of water is for the cooling in thermal power generation. In terms of process water, the industry uses water to produce steam for direct drive power and for use in various production processes and chemical reactions. Other industries which use water for products include businesses like beverage and pharmaceutical sectors, consuming water by using it as an ingredient in finished products for human consumption (i.e., products delivered in liquid form). The term “virtual water” is consequently used to describe the water that is embedded in both agricultural and manufactured products as well as the water used in the growing or manufacturing process (WBCSD, 2006).

Fig. 1 Global water consumption since 1901 (Richie and Roser, 2019).

Fig. 2 Industrial water withdrawal for 2015 (Richie and Roser, 2019).

The overall demand for water is growing every day and surface as well as groundwater resources are facing more demand and in some instances, wells have become depleted. The world's population is estimated to reach 9.1 billion people by 2050 and with this growth comes a parallel rise in demand for clean water, food and energy. Water demand is already expected to exceed current supply by 40% by 2030 as indicated previously and many parts of the world are already facing increased water scarcity. The continuous increase in water demand together with climate change as well as current mismanagement of existing water resources in water intensive industries, especially agriculture, are exacerbating risk and unpredictability. The interlinked challenges have consequently also increased competition between communities and countries for scarce water and subsequently aggravated old security dilemmas, created new ones and in some instances hampered the achievement of fundamental human rights to food, water and sanitation (Manganello, 2019).

Industrial water usage is directly proportional to the average income level of its people. Industrial water withdrawals constitute 5% in low-income countries as opposed to the above 40% in some high-income countries. Furthermore, a number of countries in Asia are now also developing their economies around industrial development so that water usage in this sector will increase over subsequent years (Kibona et al., 2009; Lui et al., 2011). Industrial water use will, therefore, increase further across the globe, which may be accompanied with an increase of water-related risks such as increased competition for the resource as well as increased pollution if untreated wastewater is continually disposed of into surrounding water bodies.

The use of water for industrial processes as well as the discarding of wastewater can have various impacts if not properly managed and controlled. The additional increase of industrial water use accompanied by continued population and socio-economic growth will consequently exacerbate current negative effects of industrial water use and cause greater future challenges. Water is also used as a disposal site for wastewater into natural freshwater systems. Rivers and other water bodies can handle small quantities of waste broken down by nature, however, these limits are often exceeded and cause water quality to decline downstream causing it to be no longer useable without expensive treatment (du Plessis, 2019). The main contributing factors of industrial water pollution as well as the associated causes and effects follows.

Industrial Water Pollution: Contributing Factors, Causes and Effects

The start of the Industrial Revolution was accompanied by drastic changes in the social and economic lives of the world's population and the benefits of this are still experienced today. However, since the industrial revolution, industrial waste and pollution has become an increased major problem.

Industrial pollution can be described as different types of waste generated by various manufacturing or industrial processes. Industrial waste can be solid, liquid or gases held in containers. This waste can be toxic, ignitable, corrosive or reactive and if improperly managed, this waste can pose dangerous health and environmental consequences. The following sections will focus

on the contributing factors of industrial water pollution as well as the significant pollutants, causes and effects thereof on the human population and surrounding waterbodies.

Contributing Factors

Almost all of the water used in industries, ends up as industrial wastewater. Upon its release into the surrounding environment, it consequently creates a significant footprint and may be accompanied with various hazards (Ranade and Bhandari, 2014; O'Donnel, 2018). Chemical and allied process industries especially contribute to this negative water footprint. Industrial wastewater contains specific and readily identifiable chemical compounds. Water is mainly polluted by subsectors in the form of toxic wastes and organic compounds which can be largely traced to processing of industrial chemicals and to the food products industry.

Recent reports indicate that the total wastewater (combining sewage, industrial, and agricultural), being discharged globally is tens of millions of cubic meters per day (UN Water, 2008; Corcoran et al., 2010). It is believed that a very large portion of wastewater in developing countries is discharged untreated which have resulted in large-scale pollution of waterbodies and consequently endangering living species which include any surrounding population dependent on these water sources. It has been estimated that as much as 80–90% of all wastewater in developing countries is discharged directly into surface water bodies (UN Water, 2008; WWAP, 2009). Unfortunately, the discharge of untreated industrial wastewater is not limited only to developing countries but takes place in developed countries as well. The effects of industrial wastewater pollution can be vast and has been the cause of some of the most significant environmental disasters of all time. The main contributing factors of industrial pollution are extensive in nature however some of the major or top reasons include the following (Ranade and Bhandari, 2014; O'Donnel, 2018):

- *Unplanned Industrial Growth*—Established rules and regulations and standard practices are in some cases ignored by companies to facilitate rapid growth. Water and air pollution frequently occur due to unplanned developments.
- *Lack of Effective and Strict Policies/Enforcement thereof*—Numerous industries around the world have been able to disregard or bypass pollution laws as policies are either not valid or adequately enforced by relevant government departments or pollution control boards. This has resulted in significant pollution affecting both the environment and human populations.
- *The Large Number of Industries*—Since the industrial revolution the sheer number of industries and factories have increased significantly. Small sectors which rely on government for grants to enable them to keep operating, are often able to avoid adhering to environmental regulations. Most of these companies have been found to release significant amounts of toxic substances, increasing pollution to significant levels.
- *Use of Old and/or Outdated Technology*—New and updated technologies are often very expensive and there are numerous companies and factories which still rely on outdated technology to continue operating their business successfully. These old and outdated technologies often produce large amounts of waste.
- *Natural Resource Use*—A lot of industries make use of raw materials which requires the removal of these from underground. The process of removing raw materials is accompanied with the pollution of soil and may also be associated with oil leaks as well as spills which can be harmful to both the environment and the human population.
- *Improper Disposal of Waste*—The improper disposal of waste is the most common and significant form contributing to pollution. Most major industries should have treatment facilities for industrial effluents. Small-scale industries however in most cases cannot afford big investments in pollution control equipment as their profit margin is low.
- *Lack of Maintenance, Upkeeping and or Updating of Practices and Equipment*—In many instances, old equipment is continued to be used on a regular basis even though it may be faulty or not functioning properly. Equipment is not inspected on a regular basis and is left to fail or break which can then be accompanied by serious pollution events. An example of this was the Deepwater Horizon event. This happens regularly on a smaller scale in industries around the world.

The extent of industrial water pollution throughout the whole of Russia can be seen as a good example to illustrate the consequences of ineffective policies or regulations and a country driven by industry. Russia holds a quarter of the world's total freshwater supply and a large portion of this has been contaminated by industrial waste. It has been estimated that 35–60% of the total drinking water reserves do not meet sanitary standards and the industrial pollution now affects all corners of the country. Russia's Ministry of Natural Resources stated in 2017 that 74% of the country's population lives in environmental deterioration, and 40% of them consume water unhealthy to drink. Russia's Natural Resources Ministry has been charged by prosecutors of neglect as no environmental fines have been collected across the country. In 2016, an industrial company named Norilsk Nickel was fined a mere \$530 for contaminating an entire Siberian river with heavy metals. The Murmansk region located in the northwest of the country has suffered from widespread nuclear hazards and has been the dumping ground of ship skeletons. Currently, corporations do not have incentive to practice eco-friendly habits due to ineffective and unenforced fines and have consequently led to the country's rivers and lakes being flooded with waste runoff from factories. Russia has the means to enforce its own environmental regulations. However, its Natural Resource Ministry has neglected to collect on 132,075 instances of entire-river poisoning. The Russian federal budget has allocated US\$880,000 as a progressive move towards cleaning the unauthorized ship dumps out of Kola Bay. However, without proper enforcement of regulations, corporations will continue to abuse the environment and ignore eco-friendly habits or practices (Bramlett, 2018).

Both developing and developed nations are characterized by widespread industrial water pollution. The mentioned contributing factors all play a role at various intensities depending on the context. The description of significant pollutants, causes and effects of industrial water pollution now follows.

Significant Pollutants, Causes and Effects

Industries are a huge source of pollution around the world as they produce pollutants which can be very harmful to both the environment and the human population. Numerous industries use freshwater to transport waste away from the facility and into surrounding waterbodies, rivers and oceans. The significant pollutants from the mentioned industrial sources above include, but are not limited to, the following (Blacksmith Institute, 2007):

- *Lead and Mercury*: Metallic elements causing human health and environmental problems. They are nonbiodegradable and are very hard to remove from the environment once it is contaminated. They are harmful to both humans and animals. These pollutants are closely associated with mining, foundries and smelters, and other metal-based industrial operations.
- *Sulfur and Arsenic*: They are released most commonly by mining operations. Blasting and other mining processes expose surrounding waterbodies, especially groundwater, to high levels of these elements. Tailings dams which fail also causes mining wastewater containing these elements to spill into surrounding waterbodies.
- *Nitrates and Phosphates*: Increased fertilizer use have caused an increase of nitrates washed from soil into surrounding waterbodies. This causes eutrophication in both freshwater and marine environments which can be very problematic and is accompanied with serious environmental effects especially on aquatic species.
- *Oils and Petrochemicals*: Oil does not dissolve in water and forms a thick layer on the water's surface. Petrochemicals are formed from gas and petrol and can be toxic. Both of these pollutants are harmful and can be toxic to aquatic life.

The industrial activities which contribute the most to the degradation of freshwater sources, both surface and groundwater, include agriculture (fertilizer and pesticides); mining (blasting/extraction of materials and failure of tailings dams); fishing (regular use of boats releasing oil and petrochemicals); nuclear power plants (release of radioactive substances and thermal pollution); fuel industry (spills or leaks of petrochemicals); plastics (both production wastewater and dumping of plastics); textile manufacturing (production has a common by-product of asbestos); cleaning industries as well as commercial cleaning products (harsh chemicals and sewage and can also fall into this activity type); and lastly auto manufacturing (use of harsh chemicals and metals in production processes such as mercury and lead) (du Plessis, 2019). Most industries therefore have the potential to contribute to the degradation of waterbodies and ultimately cause damage to freshwater sources, the natural environment and human health.

Freshwater resources around the world are faced with significant pollution problems, some more than others. Water degradation in developed countries is mainly attributed to agriculture, industries, or factories as well as water pollution from fuel emissions especially in large metropolitan areas where human populations are growing at a constant pace. Developing countries, on the other hand, differ somewhat but the end result is relatively the same. The biggest culprit of water pollution in developing countries includes the lack of or inadequate waste management as well as primarily the lack of sewerage and septic systems (du Plessis, 2019).

Industrial water pollution has a dual effect as it has an impact both on the standard of living as well as the environment itself. The effects on the human population as well as aquatic communities are many and varied. The large amount of toxic materials which are released causes an overall reduction in human productivity but also affects biomass and diversity of communities of affected waterbodies. Human health is also affected. Drinking water is often negatively affected and can become a health hazard. The direct damage to aquatic environments also affect human health (Owa, 2013; du Plessis, 2019). Polluted water can become unsuitable for various uses especially in terms of drinking, recreation, agriculture, and industry.

The battle over industrial water pollution in Alabama, the United States of America (USA), can be used as a good example of how industrial water pollution can have widespread effects on both the environment as well as human health. Flint, Michigan is not the only city which has been experiencing severe issues related to safe drinking water in the USA. Other cities from Parkersburg, West Virginia, to Hoosick Falls, New York have also been experiencing this issue. Residents and a water authority in North Alabama are suing 3M, a maker of products from Scotchgard to Post-It Notes, in connection with chemical pollutants in the water supply. 3M has been manufacturing and discharging chemicals created to make non-stick surfaces into the Tennessee River for decades and the current pollution levels are three times what is considered safe by the Environmental Protection Agency. Residents have been experiencing a range of health issues, from cancer to high cholesterol due to long-term exposure (Douban, 2016).

Contaminated water therefore not only ultimately destroys aquatic life but creates short and long-term human health hazards which results in an overall decrease in productivity in all spheres. There are multiple sources of industrial water pollution however the end result is the same, namely the overall degradation of freshwater resources with varied effects on the environment and human health.

Current Challenges and Possible Risks, Solutions or Strategies

As highlighted in previous sections, the introduction of industrialization has been accompanied by various adverse effects especially in terms of water pollution. The expanding industrial base with accompanied pollution have placed additional pressure on existing water and often causes water resources to no longer be suitable for human consumption or other uses. Industries are therefore putting increased strain on the world's water resources in terms of increased demand as well as continued degradation.

The World Economic Forum has placed water crises third on the list of top world risks in terms of impact. It refers to the water crises as an interconnected world risk to other sectors. The intensity of the water crises is currently emphasized by approximately 36 countries around the world facing extreme levels of water stress. Water has also been consistently ranked as one of the top five risks

for seven consecutive years and the headlined threats to humanity and the planet over the next decade are all linked to water (World Economic Forum, 2017; World Resources Institute, 2017). Water is and will become an increased risk worldwide. The following sections will focus on the types of challenges and risks which industries currently face and may be exposed to in future as well as possible strategies which could be considered to manage or minimize these.

Current Challenges and Future Risks

The two major challenges which the world is facing are linked to consumption patterns. The supply of freshwater is already limited, however demand is consistently increasing and numerous countries are unable to meet basic water needs as well as provide sufficient quantities of water at an acceptable quality. Water shortages in terms of quantity is therefore already a serious challenge in many regions of the world. Some of the worst hit areas include, but are not limited to, southern Spain, the Maghreb, the Middle East, Central Asia, Pakistan, Southern India and Northern China (RobecoSAM, 2015). Water pollution exacerbates water scarcity around the globe even more as it limits the availability of clean water. As indicated previously, numerous countries are characterized by the dumping of non- or inadequately treated wastewater into waterbodies. Countries around the world are therefore increasingly faced with limited water availability as well as with the impacts associated with water degradation on human health as well as the environment. The global trends which primarily contribute to the current water challenges and which will continue to exacerbate these include continued growth in the global population, increasing urbanization, continued aging infrastructure and climate change.

The world's current population stands at an estimated 7.3 billion. Even though growth rates are expected to stabilize, the population will continue to increase over the next few decades. The world's population is expected to reach 9.6 billion by 2050 and the demand for water will consequently increase. However, the growth in population is not the only driver for an increase in water demand. The past couple of decades have shown that water consumption has grown faster than the population growth rate due to continuous improvement of living standards. This trend will most probably persist in future due to continuing increases in living standards especially in emerging markets (RobecoSAM, 2015; du Plessis, 2019).

Increased urbanization occurs concurrently with population growth. An increasing number of the world's population are leaving rural areas to live in cities. Rural–urban migration is usually driven by the real or perceived lack of employment opportunities in rural areas. It is estimated that 54% of the world's population currently live in urban areas and is forecasted to be 60% by 2030. Cities are growing in numbers but also in size, particularly in Asia, Africa and Latin America (RobecoSAM, 2015). The rapid growth in the amount as well as size of urban areas have consequently created an immense challenge for the water sector as the demand for water services have escalated exponentially. Major pressure has especially been placed on wastewater treatment and the challenge also extends to providing basic sanitation services, both of which require major investments.

Aging infrastructure in tandem with growing populations and urbanization has also become an increasing challenge especially in industrialized nations. In contrast to many developing nations which are still struggling to provide adequate access to safe drinking water, industrialized nations built most of their water infrastructure in the early 20th century. Most of these water supply and sewer systems have an average service life of 60–80 years and, in many cases, have reached the end of their lifespan. Additionally, water infrastructure has also not been properly maintained in some countries (RobecoSAM, 2015; du Plessis, 2019). Major investments in the repair and upgrade of aging infrastructure are therefore required in many areas to address this issue. The lack of improvement in this regard will consequently place additional pressure on water availability for all sectors as water of a suitable quality will decrease even further in quantity.

Climate change is also expected to have an increased and significant impact on water resources across the globe. It is anticipated that climate change-induced water scarcity and floods will intensify as concentrations of greenhouse gasses increase (IPCC, 2014). Climate change and increased climate variability is likely to vary at local and regional scales and over different seasons. The predominant trends indicate that dry areas will become drier and wet areas wetter and will most probably therefore exacerbate water stress in areas which are already the most affected (WWAP, 2019). Climate change in combination with the overexploitation and continued degradation of water resources is already affecting water supplies around the world and the effect will intensify if significant changes are not made.

Recently, many parts of the world are already feeling the “water crunch” to a great extent. Growing water stress across the globe results from substantial use of water resources with major impacts on resource sustainability and the rising potential of conflicts between water sectors. The world, as a whole, may not experience water scarcity. However, due to the uneven distribution of water across the globe, some parts of the world will experience more scarcity than others. The origin of water scarcity can be attributed to natural events such as reduced rainfall or climate variability. However, the human factor is the most critical as it consistently aggravates the problem through over-use, water wastage, continued pollution and/or inappropriate or flawed water management practices (du Plessis, 2019; WWAP, 2019).

Therefore, the core risk for the industrial sector is limited water supply in terms of availability and quality. Water plays a crucial role in industrial production such as paper, textile, electricity generation, mining operations, oil exploitation and pharmaceutical drugs. It was estimated in 2009 that industrial production consumed approximately 800 km³ and is projected to be 1500 km³ by 2030 (McGuire et al., 2009). Without water the industrial sector will not be able to continue production making increased water stress around the world a major challenge and risk.

The levels of physical water stress will ultimately increase in intensity and spread to other areas as populations and their demands grow and the effects of climate change intensify. Significant attempts should be made worldwide, especially in regions

already experiencing substantial water scarcity, to reduce water usage or demand as well as to treat wastewater to make it reusable or at least up to standard to discharge into the environment. It is also of importance to try and mitigate industrial impacts on water resources as well as the decline in water quality. Uncertain future conditions, especially in terms of unknown water inflows as well as diverse industrial activities, will require continuous innovative methods to support decision making especially in industrial water resources management systems. The following section will place focus on possible solutions or strategies which could be considered to lessen or reduce these challenges and risks.

Possible Solutions and/or Strategies

As highlighted in previous sections, water plays a vital role in numerous industrial processes from the extraction of natural resources in oil and gas or mining operations, to supplying the microelectronics and pharmaceutical sectors with ultrapure water. Water also needs to be adequately treated before it is discharged. The continued deterioration of water quality caused by industrial activities have emerged in many developing countries. This is of particular concern in India and China as the majority of industrial wastewater and effluents are discharged without adequate treatment into the surrounding environments posing serious threats to the population's health and the environment. The world is consequently faced by the dual challenges of water resource shortage and water quality degradation which will be further exacerbated by the continued increase in industrial water demands. The risk of water scarcity or decreased water supply is becoming more prominent across the globe.

The continual large gap between wastewater generated and the treatment thereof highlights the need for improved water management. Large investments are required to improve wastewater treatment especially in developing countries. The industrial wastewater treatment market has received increased attention as environmental regulations related to effluent discharge have become stricter. The declining availability of both surface and groundwater will require industries to look for alternative sources of water supply if they do not become self-sufficient through water recycling and reuse. The potential for water reuse and industrial wastewater treatment especially in the oil and gas industries, which is the fastest growing segment of the water market, has consequently become an attractive source of growth in terms of water technology companies (Ranade and Bhandari, 2014; RobecoSAM, 2015).

With the growing concern for the environment and increasing stricter government norms worldwide, it has now become necessary for industries to focus on increased pollution control. This includes adopting the most suitable technologies to treat their wastewaters and considering increased investment into wastewater treatment technologies to improve water use efficiency. This will ultimately reduce the risks of decreased water supply and possible conflicts with other water sectors such as agriculture. Some of the fastest growing areas in wastewater treatment technologies include the reverse osmosis and nanofiltration market. Ultrafiltration/microfiltration is also expected to grow while standard process equipment like aerators, screening and grit removal systems are likely to have low growth rates in the future. Zero-liquid discharge systems, including brine concentrators, crystallizers and evaporators are expected to have an above average growth rate due to the stricter regulatory restrictions related to effluent discharge (RobecoSAM, 2015; Wilkinson, 2017).

Industrial wastewater will have to undergo treatment to a suitable standard for discharge into surrounding waterbodies but will also need to be considered and highlighted as a useful and potential resource. Wastewater treatment, recycling, and reuse can have significant cost benefits mostly in the form of reduced water requirements. Process modifications can also substantially reduce the cost of wastewater treatment apart from a change of methodology for effluent treatment, land/space requirements, equipment costs, and legal binding legislation concerning pollution levels. Water efficient technologies therefore do not necessarily have to involve capital-intensive investments as existing systems and operations can be optimized. Full understanding through adequate monitoring and establishment of water use and disposal in the organization for each operation will be required. Buy-in from all sectors will also be necessary (Wilkinson, 2017).

A strong commitment at all levels will however be required from industry to government. Stricter and enforceable government regulations on pollution control and access to affordable and effective solutions are essential. Incentives in terms of economic tools and command as well as control tools will have to be created to support the creation of an enabling environment for water use optimization in the industrial sector. The creation of these incentives together with behavior changes can be difficult if results are not felt by the users. Awareness related to water efficient strategies and/or equipment among operators as well as the structuring of rewards can assist in changing current user behavior. For strategies related to water optimization and reduction of costs to be efficient in implementation, current water use and set global goals need to be assessed. The overall reduction of industrial water consumption can be seen as one means of reducing overall risk and addressing the global water crisis.

Conclusions

To be able to sustain the world's growing population, the world's economy will need to continue to grow. Water is critical for future growth and therefore can also be a major limiting factor for future growth. Water as a limiting factor has already become clear in businesses in water scarce regions which are facing risk. Investors are consequently increasingly considering water supply during their decision-making processes.

Industrial wastewater treatment especially in terms of recycling and reuse has become important themes in today's increasing water stress context. These measures are receiving increased attention, not just in an attempt to protect water resources from

continued degradation, but also to conserve water resources for water stress to be reduced or minimized. A number of technologies are available; however the selection will depend on the desired goals of wastewater treatment.

All water sectors, individuals and governments need to act as a collective to decrease water wastage and pollution, to reuse more industrial water, to increase effective management practices and become more water efficient. Higher water productivity levels can be achieved and water stress will ultimately be reduced. The continued evolution of technology and infrastructure improvements will hopefully enhance the world's overall water supply capacity and assist countries to deliver clean drinking water and sanitation services to both rural and urban populations. Political will however will be required on all fronts to promote future water efficiency to ultimately reduce the prominent risk of increased water stress and scarcity.

Abstract

Global electric power generation relies heavily on water. Hydropower utilizes the potential and kinetic energy in running water and thermoelectric power plants, e.g. coal-fired, gas-fired and concentrated solar power, withdraw significant volumes of water for cooling purposes. Water is also used in various other stages of electric power generation's life cycle, such as coal mining, transportation, crop irrigation and so forth. Consequently, water shortages and rising water temperature can lead to curtailment of electric power generations. Climate change is expected to deteriorate water scarcities in some regions, which, compounded with rising water temperature, can exaggerate such electric power generation's water-related risks. Adopting air cooling systems, transforming the energy portfolio to gas, solar PV and wind, and utilizing alternative water sources, e.g. seawater and reclaimed water, can help reduce the electric power generation's reliance on freshwater resources in order to cope with future potential water-related risks.

Introduction

Modern human society runs on electricity (hereinafter referred to interchangeably with 'electric power' and 'power') that is consumed from agricultural and industrial productions to household consumption. It underpins humanity's development and prosperity. Higher electricity consumption level is correlated with higher human development and welfare indicators (Niu et al., 2013). Between 1990 and 2010, 1.7 billion people have gained access to electricity. Global electricity consumption has almost doubled from 11,894 TWh in 1990 to 21,481 TWh in 2010, and then 26,770 TWh in 2018 (IEA, 2019). It is worth noting that, in recent years, electricity consumption increased at an even faster rate than other energy products globally due to the proliferated electrification of various energy uses, e.g. air conditioning and electric vehicles. However, despite such impressive progress, 1 in 7 people living on this planet today still lacks access to electricity. The United Nations has proposed to ensure universal access to electricity by 2030 as a target of the 7th global Sustainable Development Goal (SDG) (United Nations, 2015).

There is a growing appreciation in the energy community that water is an important production factor for electricity generations. According to UN WWAP (United Nations World Water Assessment Program, 2014), about 90% of global electric power generation depends intensively on water. It is not difficult to understand that water is indispensable for hydro-electric power productions. In 2015, 150 countries had hydropower generations that made up 16.6% of the world's total electricity and 70% of all global renewable electricity. Apart from hydropower, many thermoelectric power plants, which provide over 80% of global electricity, require cooling water to cool and condense steam exiting the steam turbines and therefore withdraw significant volumes of water every year. Thermoelectric cooling is estimated to be responsible for around 43% and 50% of total fresh water withdrawals within the EU and the US, respectively (UN WWAP, 2014).

On the other hand, lack of water has been identified as one of the biggest risks facing humanity during the next decade (World Economic Forum, 2015). The fifth assessment report by the Intergovernmental Panel on Climate Change (IPCC) has anticipated that a changing climate is likely to change the spatio-temporal distributions of water resources by changing precipitation and evaporation patterns. Some already water-scarce regions may experience heightened drought risks, including increased drought periods and expansion of drought-affected areas, which will consequently amplify existing problems caused by water scarcity. UNESCO estimates that over half of the global population will face freshwater stress by 2025, and, by 2050, the number will increase to a worrying 75% (UN WWAP, 2003).

Water scarcity can have detrimental effects on the society and economy. Along with increased river water temperatures, water scarcity may lead to electricity production curtailments for instance. Numerous such incidents have been documented throughout the globe (McCall et al., 2016). For example, during the 2007 and 2012 droughts in western US, many thermal electric power

generators were exposed to water-related shut downs and curtailments, so were many nuclear electricity generators in France during the 2003 drought. Projections based on climate change modeling indicate reductions in usable capacity for 61–74% of the global hydropower and 81–86% for thermoelectric power from 2040 to 2069 depending on different climate change scenarios (Van Vliet et al., 2016). Overall, the water demand by the electric power sector is expected to increase with the growing economy and population, while climate change is expected to alter the spatiotemporal distributional pattern of water availability, e.g. low flows, thus reducing water security in some regions and raising freshwater for electricity generation as a global emergent challenge. Sadoff et al. (2015) have assessed the global water security and pointed out that China's water-scarce but relatively economically developed and densely populated north stands out as facing the highest water risk for its electricity generation.

Life-Cycle Water Use for Electric Power Generation

Water is required at different stages of the life cycle of electricity productions. Overall, the life cycle of electric power generation can be divided into three stages: upstream, power plant operation and downstream (Meldrum et al., 2013). Upstream stages include (1) fuel cycle, i.e. extraction, processing and transportation; (2) manufacturing of power plant components, e.g. steam turbines, wind turbines and solar PV panels; and (3) construction of power plants. Power plants operational water uses refer to on-site water usages that include water used for cooling, washing, and drinking etc. Downstream water uses primarily refer to water used in power plant decommissioning stage.

There are mainly two methods that can be used to quantify the life cycle water use for electricity productions: bottom-up process-based life cycle inventory analysis and top-down environmental-extended input-output analysis. With bottom-up life-cycle inventory analysis, (Mekonnen et al., 2015) estimated that 340 billion cubic meters (BCM) of water is consumed every year for the fuel extraction, power plant construction and power plant operation of global electric power generation's life cycle. Fthenakis and Kim (2010) estimated water intensities of both conventional and renewable electric power plants' life cycle in the U.S. based on data from the existing literature. They pointed out that, uranium enrichment, especially by gaseous diffusion, requires the largest share of nuclear power plants' upstream water usage. According to the US Department of Energy (1983), underground coal mining requires more water than surface mining for dust control inside the coal mines, which accounts for about 70% of the total on-site mining water use, while the rest is used for coal washing. Moreover, underground mining also requires more upstream water use than surface mining because of the extensive use of mine equipment that requires water inputs in their manufacturing stages. There are substantial variations in the exact values of water uses, depending on sources of the data, and conditions, such as heating value and seam thickness of the fuel (Fthenakis and Kim, 2010). Regarding renewable energies, water usages during the upstream stages are mainly related to device manufacturing and power plants construction, except for the biomass whose fuel cycle requires large amounts of water for irrigation. Grubert et al. (2012) found that replacing coal-fired power plants with natural gas combined cycle plants (NGCC) can reduce Texas coal power's water footprint by 60%, 0.2 BCM per year. Meldrum et al. (2013) broadened the study scope by including power plant decommissioning and harmonized literature estimates and concluded that (1) thermoelectric power productions are more water intensive than PV and Wind; and (2) Operational phase dominates electric power production's life-cycle water uses. The study of Feng et al. (2014) in China using hybrid Life-Cycle and Input-Output analysis also came to a similar conclusion, except they also included biomass and found that life-cycle water consumption of biomass tops the list, of which crop production accounts for 95%.

Another stream of scholarly work has used the Environmental-Extended Input-Output method to quantify the life cycle water uses for electric power production. Wan et al. (2016) found that Intended Nationally Determined Contributions (INDC) will lead to more life-cycle water consumption for the electric power sector in China, India and Russia because their renewable energy development requires substantial upstream water inputs. Chai et al. (2018) calculated that coal-fired power generation in China withdraws and consumes 35.46 and 17.67 m³, respectively, per MWh of electricity generated throughout the life cycle.

Operational Water Use for Electric Power Generation

Hydro-Electricity

Water carries a huge amount of energy that can be transformed into electricity. There are four types of technologies utilizing energy in water to generate electricity:

- (1) *Storage Hydropower Stations*: Storage hydro-electricity is generated from the potential energy of dammed water that is released in operation to drive a water turbine and generator;
- (2) *Run-of-the-River Hydropower Stations*: Some hydropower stations have small or no reservoir capacity are called Run-of-the-River hydroelectric stations so that only the water coming from upstream can be used for generation at that moment;
- (3) *Pumped storage hydropower stations* use excess electricity when electricity demand is low to pump water to higher reservoirs and release water when electricity demand is high;
- (4) *Offshore hydropower stations*: a less established group of technologies that are gaining market share generating electricity from seawater, which includes wave electricity that captures energy from ocean surface waves and tidal electricity that uses turbines to capture tides energy in the coastal areas.

Except offshore hydropower stations, hydroelectricity depends almost entirely on freshwater resources on earth. The power extracted from the water depends on the volume and the difference in height between the source and the water's outflow. This height difference is called the head. The capacity of hydro-electric plants can be calculated based on the equation below:

$$P = m \times g \times H_{\text{net}} \times \eta$$

where: P is power (Watts); m denotes water flow rate (kg s^{-1}); g refers to the gravitational constant, which is 9.81 m s^{-2} ; H_{net} is the net head and η is the product of efficiencies of all different components, including the turbine, drive system and generator. Net head is calculated as the gross head that can be measured at the site deducting any head losses, which is normally assumed to be 10%.

According to the [International Hydropower Association \(2018\)](#), an unprecedented amount of electricity, 4185 TWh, was generated from hydropower in 2017. Global hydropower capacity has reached 1267 GW, including 153 GW of pumped storage. The regional distribution of installed hydropower capacity is demonstrated in [Fig. 1](#).

It can be seen from [Fig. 1](#) that the largest amount of hydropower capacity is installed in the East Asian region. In 2017, 21.9 GW of new capacity was added globally and China, the world's largest hydropower producer, accounted for nearly half of the newly added capacity, at 9.1 GW. It was followed by 3.4 GW in Brazil, 1.9 GW in India, 1.1 GW in Portugal and 1.0 GW in Angola. [Fig. 2](#) demonstrates the countries with the largest hydropower productions whose national electricity productions are therefore highly dependent on freshwater resources.

Not only much less constrained by intermittence issues than other renewable energies, such as solar and wind, hydropower is also a much more flexible electricity source compared to conventional thermal electric power plants. Hydropower stations can be ramped up and down very quickly, normally around a few minutes, to adapt to different levels of electricity demands ([Robert, 2010](#)). Moreover, power generation at hydropower plants does not generate any greenhouse gases at the operational stage. Hence hydroelectricity is widely regarded as an ideal alternative to conventional fuel-combustion thermal power plants despite its various controversial social, environmental and ecological impacts. Global hydropower production is expected to continue growing against the backdrop of continuing economic development and climate change mitigation ([International Hydropower Association, 2018](#)). Human society's electric power generation's reliance on fresh water running in river systems is expected to elevate accordingly.

Thermoelectricity

Coal-fired power plant

The largest share (40%) of global electricity is produced from coal. Water is often extensively used in coal-fired power plants as well. The water-using processes in a typical coal-fired power plant can be categorized as below:

- (1) *Industrial water use*: such as lime-ash removal and wet desulfurization, as well as cooling of the steam that drives the turbine and other auxiliary engines (including induced air fan, forced draft fan, primary air fan, and so forth). Cooling systems are needed to dissipate the residual heat of the steam exiting the turbine and water is often used as the medium. Cooling water constitutes the biggest part of thermoelectric power plants water uses.
- (2) *Domestic water use*: power plants workers require water to drink and for other domestic uses.
- (3) *Chemical water use*: Due to salinity enrichment, boilers need to be regularly emptied and replenished with demineralized water of the highest quality.

The abovementioned water flows and related energy flows are illustrated as in Fig. 3 below.

The amount of cooling water used depends largely on the cooling system employed. Water use may refer to both water withdrawal and water consumption. Water consumption is defined as water withdrawn from the environment but not discharged back into any water bodies. There are three types of cooling systems being used: open-loop and closed-loop wet cooling, and air-cooling:

Open-loop cooling systems, also called once-through, withdraw the largest amount of water but more than 99% is returned to the water source;

Closed-loop, or recirculated cooling, withdraws significantly less water; however a larger proportion is consumed due to evaporation, either in cooling ponds or cooling towers;

Air-cooling systems, also called dry cooling, have the lowest water consumption and withdrawal intensities as they do not need any water for cooling purposes. However, water is still required for other on-site uses, e.g. cleaning. Moreover, reducing water use by deploying air cooling systems comes at a price. As air cooling systems have lower cooling efficiencies, the steam leaving the turbine has a higher temperature, which creates a back pressure. As a result, power plants with air cooling systems face 5%–10% of thermal efficiency losses (Electric Power Research Institute, 2004).

Cooling technology affects the water consumption factors in two ways: first, nearly 100% of water abstracted by closed-loop cooling system evaporates during the cooling circles while only 3% of water withdrawal of open-loop system is consumed. Therefore, when compared to closed-loop cooling system, consumptive water use in an open-loop system is 70–80% lower than in a closed-loop system, but water withdrawal is 30–60 times higher (World Resource Institute, 2015). Secondly, since cooling systems marginally impact the plant's efficiency, power plants with an open-loop cooling system consume less water in other processes due to their higher efficiency. Due to the large share of ancillary water uses, air cooling systems' water consumption is on par with that of open-loop cooling systems.

Water consumption compositions of a typical coal-fired power plant equipped with open-loop cooling systems and closed-loop cooling systems are demonstrated in Tables 1 and 2 respectively (East China Electric Power Design Institute, 2012). It can be seen that 80% of water consumption in a power plant equipped with closed-loop cooling systems is used for cooling purposes.

Since water is used to dissipate any residual heat, improving boiler technology increases conversion efficiency and decreases residual heat and therefore lowers water requirements. Moreover, more water is needed if the intake water temperature is higher, for instance, during summer times, which is expected to happen under climate change together with drought situations and pose threat on coal-fired power plants water supplies.

Fig. 3 Water and energy flows in a coal-fired power plant (Liao, 2018).

Table 1 Designed water consumption factor of power plants with open-loop cooling system of different capacities.

Capacity (MW)	Wet desulfurization (without GGH, m ³ /h)	Dry ash/lime-ash removal (m ³ /h)	Coal transport (m ³ /h)	Boiler make-up (m ³ /h)	Domestic water use (m ³ /h)	Total (m ³ /h)	m ³ /MWh
2 × 300	100–110	109–195	46–83	80–150	5–10	340–548	0.567–0.913
2 × 600	190–230	155–247	60–107	90–170	5–10	500–764	0.416–0.637
2 × 1000	270–320	265–380	77–146	150–270	5–12	767–1128	0.384–0.564

Natural gas electric power plants

There are primarily three types of natural gas-fired electric power plants: natural gas combined-cycle (NGCC) power plants, gas combustion turbines and gas-fired steam turbines. While gas turbines are directly driven by hot combustion gases, an NGCC plant first uses a gas combustion turbine to generate electricity and then uses the waste heat to create steam to generate more electricity in a steam turbine. Because gas combustion turbines require no cooling because there is no steam to be condensed, the overall combined cycle system requires much less water for cooling than traditional steam turbine technologies. According to Macknick et al. (2012), water use values (median) of a natural gas-fired power plants are as below in Table 3.

According to the US Energy Information Administration (2012), more than 80% of natural gas-fired power plants in the US are NGCC plants. Gas turbine and steam turbine power plants occupy 9% each. Utilizing natural gas is an effective way to reduce electric generation's reliance on freshwater resources at the operational stage.

Concentrated solar power (CSP) plants

CSP requires larger amounts of water at the operational stage compared to other commonly used renewable energies, i.e. Solar PV and Wind. Both CSP and solar PV require water to clean the mirrors and panels as dust can reduce the system efficiency. Water intensity for mirror and panel washing ranges from 0.08 to 0.15 m³ MWh⁻¹ (Bracken et al., 2015). Such variation depends on the frequency of cleaning which is decided by the site conditions, such as soil and dust properties, vegetation, air pollution, wind speed and direction, humidity, and temperature as well as precipitation characteristics, i.e. intensity, frequency, and duration. Other factors such as panel/mirrors orientation and angle of tilt, glazing properties also have impacts on the cleaning frequency (Sarver et al., 2013).

Apart from cleaning needs, the thermal cycle of Parabolic trough, linear Fresnel, and power tower CSP technologies are essentially the same as those used in coal and nuclear power plants and therefore require water for cooling purposes as well as boiler make-up as in a coal-fired power plant.

Dish systems do not generally require water for cooling, nor for steam cycle operations, but do require a small amount to wash the concentrators.

Macknick et al. (2012) conducted a review study on electric power plants in the US and consolidated the values of water withdrawal and consumption of different generating technologies and energy sources as displayed in Fig. 4.

Generally speaking, to generate a certain amount of electricity, gas-fired power represents the lower end of water usage while nuclear power presents the opposite.

Table 3 Water use at natural gas-fired power plants.

	Once-through		Closed-loop		Air cooling	
	Withdrawal	Consumption	Withdrawal	Consumption	Withdrawal	Consumption
NGCC	11,380	100	253	198	2	2
Steam	35,000	240	1203	826	2	2

Water-Related Risks for Electric Power Generation

Electric power generation has been exposed to water-related risks worldwide, which has raised concerns in the global energy community in meeting the SDG7 providing universal access to reliable electricity. Water-related issues can affect electric power generation in several ways:

- (1) *Life cycle supply chain disruption*: Water-related natural hazards, e.g. flood, storm, drought, can disrupt the life cycle supply chain of electric power generation, e.g. bio-mass cultivation, coal transportation;
- (2) *Insufficient river discharge for hydropower production*: hydropower production capacity depends on the volume of water flowing in the river. Reduced river discharge can directly affect power plants capacity. It is projected that, due to reduced river flows brought by future climate change, 61–74% of global hydropower capacity may be compromised (Van Vliet et al., 2016);
- (3) *Insufficient river flows for thermoelectric cooling*: Low river discharge may fail to meet power plants water withdrawal requirement. For example, Byers et al. (2016) projected that, with Carbon Capture and Storage (CCS) development, water available in UK's river Trent is likely to fall short of cooling water demand for the basin's electricity generation by the 2030s–2040s; Tarroja et al. (2018) pointed out that water availability can also limit the development of thermally based renewable energies, e.g. geothermal and CSP, in water-stressed regions;
- (4) *High river water temperature for thermoelectric cooling*: Increased water temperature can reduce thermoelectric power plants' usable capacity due to legal thresholds for heat discharges (Van Vliet et al., 2012). The usable capacity of global thermoelectric power plants is projected to be reduced by 81–86% during 2040–2069 due to a compounded effect of changed water availability and increased water temperature (Van Vliet et al., 2016);
- (5) *Flood hazards on power infrastructures*: Flood hazards can generate damaging effects on power infrastructures in general. Flood hazards can lead to electricity brownout or blackout for various periods of time.

The situation is expected to worsen under a changing climate. The number of extreme weather events and natural hazards, e.g. flood, storm and drought, is likely to increase (IPCC, 2013). Air temperature and water temperature are expected to rise in hot summer days, which can reduce the cooling efficiency for thermoelectric power plants. On the other hand, human society is expected to have a higher demand for electricity for air conditioning and so forth.

Reducing Electric Power Generation's Reliance on Freshwater

Against the aforementioned backdrop, it is of vital importance to decouple the electric power sector with its freshwater requirements and thus lower the potential water risks for electric power generation. Liao and Hall (2018) have investigated the historical water use in China's electric power sector and concluded that transforming the energy structure to renewable energies and utilizing low-water technologies have contributed to reducing China's electric power sector's reliance on freshwater resources. Several ways for the electric power sector to adapt to future potential freshwater constraints are listed as below:

- (1) *Develop renewable energies that have lower water use intensities*, such as solar PV and wind power. Solar PV and wind power have the lowest operational water use intensities among all renewable energies. However, thermally based renewable energies, such as geothermal and CSP, should be developed cautiously based on water-sensitive planning;
- (2) *Develop gas-fired power as base load*: due to renewable energies intermittence issues and limited electricity storage, conventional fuel-based electric power production is still expected to dominate the energy portfolio to ensure electricity reliability. Compared to coal-fired power plants, gas-fired power plants not only have lower greenhouse gas emissions, but also significantly lower water dependencies. Developing gas-fired power production can have co-benefit of higher resiliency to water-related risks;
- (3) *Utilize alternative water supply systems*: limited by freshwater supplies, the electric power sector should make more use of alternative water sources, such as seawater, groundwater and reclaimed water etc. Developing electric power plants using seawater, such as tidal power and wave power, as well as coastal thermoelectric power plants that use seawater for cooling are all effective solutions to cope with potential freshwater shortages. In inland areas, utilizing groundwater and reclaimed water from industrial and municipal wastewater can also reduce the electric power sector's reliance on freshwater resources. Take China's dry north as an example, 30% and 15% of the region's thermal electric power sector's water use comes from groundwater and reclaimed water respectively (Liao et al., 2016). However, groundwater over-exploitation and reclaimed water's heavy energy use need to be taken into consideration in developing utilization plans for these alternative water sources;
- (4) *Adopt air cooling systems*: Since air cooling systems cool down the steam exiting the turbine using air and thus avoiding any water use for cooling purposes, retrofitting existing power plants with air cooling systems can significantly decrease the electric power sector's reliance on freshwater supplies. However, apart from the energy efficiency penalty mentioned above, capital cost of power plants with dry cooling systems is also much higher, can be at around 2.5 times of that of plants with wet cooling systems (Zhai and Rubin, 2010);
- (5) *Trade-off between open-loop cooling and closed-loop cooling*: It is worth mentioning that the trade-off between water consumption and withdrawal needs to be considered when choosing between open-loop cooling and closed-loop cooling systems. Open-loop cooling systems require a larger amount of water withdrawal and thus higher reliance on water supplies. However, most of the water withdrawn by open-loop cooling systems is returned back to the rivers and thus having lower water

consumption and impacts than closed-loop cooling systems. Water-sensitive plans should be made before any new power plant is proposed, planned and constructed incorporating future climate change in order to develop electric power generation that is resilient to any potential water-related risks.

Abstract

Freshwater ecosystems, whether surface, groundwater or in the form of ice caps are fundamental for human life and for supporting the vast biodiversity, natural processes and cycling. They provide ecosystem services, thus, benefits for humans and their societies obtained from nature, in all four categories: provisioning, regulating, cultural and supporting. The importance of sustaining ecosystem integrity via protecting the ecosystem services, is undeniable. However, it comprises a big challenge provided the human-induced degradation of the natural environment that, in turn, affects the earth's natural capital: natural resources, associated services with the supporting processes.

Introduction

Freshwater ecosystems, whether surface, that is rivers, lakes, streams and wetlands, groundwater or in the form of ice caps are fundamental for human life and for supporting the vast biodiversity, natural processes and cycling. They provide ecosystem services, thus, benefits for humans and their societies obtained from nature, in all four categories: provisioning, regulating, cultural and supporting. The importance of sustaining ecosystem integrity via protecting the ecosystem services, is undeniable. However, it comprises a big challenge provided the human-induced degradation of the natural environment that, in turn, affects the earth's natural capital: natural resources, associated services with the supporting processes.

This article extensively presents the functionality of freshwater ecosystems that is inseparably linked to the ecosystem services provided by freshwater bodies and their importance for human and nature well-being. The ecosystem services provided by freshwater are of vital importance for supporting all life cycles, social processes and economic prosperity.

Fresh Water Bodies: Rivers & Streams, Wetlands and Ponds, Groundwater, Ice-Caps

Freshwater ecosystems, comprise only 2.5% of water on the planet, with most of it (68.7%) and (30.1%) being captured in ice caps and as groundwater, respectively. Most of the remaining 1.2% freshwater has the form of ground ice and permafrost (69.0%), 3% of it has the form of atmospheric moisture, while readily available surface water bodies, which comprise precious and critically important water resources add up to only 0.29%. A total of less than 0.01% of the Earth's freshwater is found in lakes, wetlands, swamps, and rivers (Shikomanov, 1996; Brown et al., 2014). The biggest freshwater abundance is found in the Americas (45% of total freshwater resources); Asia has significantly smaller freshwater system (28%), Europe has 16% and Africa just 9%. The small freshwater amounts and the unequal distribution of freshwater resources result in 45 countries to have been listed as "water scarce countries,"

in which water availability is at the maximum level of 500m³/inhabitant, and 44 countries to depend on other countries for more than 50% of their water use (Brown et al., 2014).

Life and people heavily depend on all types of freshwater. The importance of freshwater as an element of life, providing this unique service to the planet, is proven by and attributed to the unique properties of water due to hydrogen bonds in the water molecule which support cell and body structures and functions, such as water being liquid over large temperature range; slow changes in temperature; it has a high boiling point of 100 °C and a low freezing point 0 °C; it presents adhesion, cohesion and surface tension; it expands as it freezes; it is a good solvent and filters out harmful UV radiation. Freshwater bodies, therefore, directly support species, human survival and quality of life. They provide services linked to numerous life services through the support of biodiversity, the hydrological elements and processes, such as natural irrigation services through precipitation and climate regulation, as well as economic services such as water for industrial production, commercial uses and agriculture, with 86% of global water use being used in agriculture and processing of agricultural goods.

Surface Water Bodies: Rivers and Streams, Lakes, Ponds and Wetlands

Surface water bodies, although comprise a small portion of freshwater they form the most direct water resource due to its easiness in accessibility. Lakes host a volume of water of $0.125 \times 10^6 \text{ km}^3$ that is less than 0.01% of the total water volume on Earth, while rivers account for the tiny amount of $0.0017 \times 10^6 \text{ km}^3$, that is $0.0001 \times 10^6 \text{ km}^3$ of the total. The largest freshwater lakes such as Lake Superior (Canada and United States), Lake Victoria (Kenya, Tanzania and Uganda), Huron (Canada and United States), Michigan (United States), Tanganyika (Burundi, Democratic Republic of the Congo, Tanzania, Zambia), Baikal (Russia), comprise vital resources for natural, social and economic growth.

Lake, wetland and estuary ecosystems are particularly rich in biodiversity and they provide multiple services. They host about 10,000 fish species and about 90,000 species of invertebrates, the vast variety of which inhabit the littoral zone and the shores. The benthic zone, the bottom area of lakes and wetlands in transition between the actual water body, the sediment and substrate, are of high ecological significance in sustaining life cycles through invertebrates, amphibians, crustaceans and molluscs. Wetlands, in particular, are characterized by high primary productivity. Wetland vegetation follows particular patterns, such as emergent plants with roots, floating plants with roots, floating plants without roots, and submerged plants with roots. Macrophytes and angiosperms (flowering plants), algae (green, yellow-brown, red, and blue-green) and detritivores are found in high abundance; they support processes of unaccountable value such as, the photosynthetic process, community respiration, fast nutrient cycling and the food webs (Murphy, 1998).

Water flowing ecosystems, lotic, or else rivers and streams, whether permanent, intermittent or ephemeral, provide undeniable benefits. The water flowing ecosystems are the most common transboundary systems with obvious importance for national security. They may comprise fields of political dispute regarding water and territorial sharing or may act as connecting elements. The world's longest river, Nile (approx. 6853 km) serves as the only freshwater resource in proximity for most of the 12 countries within its river basin. The Amazon River is the world's biggest river in volume (219,000 m³/s discharge), drains eight countries, supports the Amazon rainforest and hosts a huge variety of species, including unique species such as the pink dolphins (*Inia geoffrensis*) and the Amazon giant otter (*Pteronura brasiliensis*). The shores of the Amazon are home to reptiles, mammals, birds, reptile, amphibians, invertebrates. Rivers comprise important water and food resources for the countries they serve, they provide rich habitats characterized by great biodiversity, and often are transboundary regions of high strategic importance for the countries they serve, they offer amenity and recreational areas.

Surface water bodies, whether rivers and streams or ponds and wetlands, offer nutritional products for the ecosystem and humans, food, fresh water, genetic resources and medicines, as well as habitat and biodiversity services through the creation of natural green and blue corridors connecting the, otherwise, disconnected or fragmented ecosystems. They offer supporting services, such as photosynthesis, oxygen provision, nutrient cycling, community respiration and they provide benefits through the regulation of life and ecosystem processes and cycles, that is, improvements in air quality, protection from shore erosion, climate regulation, CO₂ sequestration, flow attenuation and flood reduction. Flood prevention and increase in resilience to flooding are regulating services of great importance; surface water bodies are natural floodplains that provide flow attenuation and storm water management that result in flood control and collection of rainwater, while they reduce the pollutant load downstream (Grizzetti et al., 2016, 2019). Stormwater runoff management and flood prevention, also through the use of green infrastructure that aims to increase the potential for surface water accumulation have become priority concerns in urban planning (Chang et al., 2018; Berland et al., 2017) and in the ecosystem protection efforts. In addition, they act as carbon sinks as they have a high CO₂ absorption and storage capacity and offer obvious benefits in the efforts to combat climate change.

Surface water bodies, due to their high visibility to humans, have a significant contribution to human well-being through amenity and recreation (Arlinghaus, 2006; Pretty et al., 2007). Humans always tended to settle near water bodies, proof of that being the fact that 50% of the world population lives within less than 3 km from surface freshwater ecosystems (Kummu et al., 2011). The vicinity of surface open water bodies was always an attraction of increased amenity value, from early settlers to the proponents of urban design based on water features, such as the "Garden City Movement" of Ebenezer Howard, and the restoration actions of Niagara Falls (Apostolaki and Jefferies, 2009; Apostolaki and Duffy, 2017) to the latest decade that has seen explicit assessments of the importance of the water-human interactions in urban environments through numerous decision support tools aiming to quantify this relationship (Farrell et al., 2010; Braat and de Groot, 2012; Russi et al., 2013). Attractiveness of surface freshwater ecosystems and their biodiversity richness attract visitors, sport practitioners and nature lovers,

bearing clear benefits to their physical, mental and psychological well-being. The presence of surface water bodies and the contact with biodiversity are considered to provide health benefits, thus improve mental, spiritual, cultural, and physical health (Völker and Kistemann, 2013; McFarlane et al., 2019) and even increase property prices (Apostolaki and Jefferies, 2009; Venohr et al., 2018), at occasionally high levels.

Groundwater

Groundwater, the “unseen” part of the hydrological cycle, is in connection and constant exchange of water with surface water bodies; groundwater aquifers are formulated due to percolation from the bottom of rivers, lakes, wetlands, estuaries and in return surface water bodies are replenished by groundwater flows (West and Obling, 2014). Although “unseen,” groundwater comprises the most important source of usable freshwater at global scale. Groundwater aquifers are crucial for the provision of water to cover all needs and provision for agriculture. Most of the irrigation water comes from the groundwater aquifers. In addition, the underground water storage sustains rich soil ecosystems in support of soil formation, providing habitats for groundwater dwelling species and land surface formations.

Groundwater is a slowly replenished resource; in most instances replenishment rates are significantly lower than exploitation rates, often resulting in fast drop of the water table and drying up of the resource. Results are several: the surface water bodies in conjunction are affected and the condition of these surface resources degrade; the availability of groundwater aquifers reduces; there is subsidence of land resulting in land reformations and loss of services provided by land use; saltwater intrusion that pollutes the groundwater aquifer (salinization of the groundwater aquifer).

Ice Caps

Ice caps comprise the highest share of freshwater of earth. The ice coverage ranges from 4 million km² in each of the polar regions in the summer, to 16 million km² in the Arctic and nearly 20 million km² in Antarctica, in winter. The food webs and species forming the land and under-water ecosystems of the arctic regions differ significantly between them; from single-celled prokaryotes to large marine mammals in the former case, to Prokaryotes (Bacteria and Archaea) and eukaryotic trophic plankton, crustaceans and fish in the latter. Spring-summer phytoplankton bloom is affected by seasonal changes in the ice cover and in ice thickness, which in turn are regulated by air temperature, ablation rates and heat fluxes from the water column and they control spring-summer transmission of solar radiation through ice. The level of sunlight allowed to reach below the ice surface affects photosynthesis and consequently, biodiversity richness and food webs (Obryk et al., 2016).

The direct transformations of water through all its forms, from water into ice and vapor in the atmosphere, establish strong links between climate change and ecosystem stability; arctic ecosystems respond in uncontrolled and unpredicted ways in any loss of arctic ice.

Ice caps, although cannot be used as a direct source of drinking water, they affect the livelihood of all other ecosystems through the climate regulation service they provide. On the other hand, the melting of ice that has been recorded since 1978, and is constantly intensifying, affects the underlying aquatic ecosystems, global climate, and in extent the world ecosystems and the services provided by them.

Connecting Nature and Society: Ecosystem Services

The relationship between humans and the natural environment can be characterized via ecosystem services (Haines-Young and Potschin, 2010). Ecosystem services refer to the benefits (both in terms of goods and services) which people obtain from nature, and as such the production of ecosystem services is a result of the interplay between social and ecological systems (MEA, 2003; Bennett et al., 2015). The most widely accepted classification of these benefits is provided by the Millennium Ecosystems Assessment working group (2003), which divides ecosystem services into four main categories namely:

- Provisioning services
- Regulating services
- Cultural services
- Supporting services
